Contents

Introduction	xxxvii
A	1
Absorption	1
Absorption Cleaning	2
Absorption Dehydration	3
Absorption Oil	4
Absorption Process	4
Absorption Tower	5
Accuracy and Precision in Analysis	5
Acetogenesis	7
Acid Catalyst	8
Acid Deposition	8
Acid Gas	9
Acid Gas Removal	10
Acid Gas Removal Processes	12
Acid Gas Scrubbing – Basic Solid or Solution	14
Acid Gas Scrubbing – Wet Scrubbers	15
Acid Hydrolysis	16
Acidity and Alkalinity	17
Acid Number	18
Acidogenesis	18
Acidogenic Digestate	19
Acid Rain	21
Acid Rain – Formation	22
Acid Rain – Mitigation	23
Acid Treating	23
Acid Value	24
Activated Sludge Process	25
Additives – Catalysts in Combustion Systems	25
Additives – Fuels	27
Add-On Environmental Control Methods	27
Adip Process	28
Adsorption	29
Adsorption Isotherm	29
Adsorption Process	31
Advanced Cycloning	32
Advanced Flue Gas Desulfurization	32
Aerobic Digestion	32
Aerosols	34
Agave Bagasse	34

Agricultural Residue	35
Agricultural Residue – Types	37
Agricultural Waste	38
Agrofuel	38
Air Emissions	39
Air Emissions – Biomass Plant	40
Air Flotation Processes	40
Air Pollution	41
Alcohol Blended Fuel	41
Alcohol-Diesel Emulsion	42
Alcohol Fuels	42
Alcohol Fuels – Ethanol	43
Alcohol Fuels - Methanol	45
Alcohol Fuels – Propanol and Butanol	46
Alcohols	47
Alcohols – Combustion	48
Alcohols – Corrosivity	49
Alcohols – From Waste	50
Alcohols – Production	50
Algaculture	53
Algae	53
Algae Fuels	54
Algae Fuels – Extraction	55
Algal Blooms	55
Alkali Washing Process	56
Alicyclic Hydrocarbons	56
Aliphatic Hydrocarbons	57
Alkalinity	59
Alkaloids	59
Alkanes	60
Alkanolamines	62
Alkazid Process	62
Alkenes	63
Alpha Decay	64
Alpha Particle	64
Alternate Fuels	65
Alternate Fuels – Gaseous Fuels	65
Alternate Fuels – Liquid Fuels	66
Alternate Fuels - Production	67
Alternate Fuels – Solid Fuels	68
Alternative Energy	68
Amine Washing	68
Ammonia	70
Anaerobic Digestion	70
Anaerobic Digestion – Gas Production	72
Animal Waste	73
Annual Removal	73
Apparent Density	74
Aquaculture	74
Aquasphere	75
Aquatic Organisms	81

Aquatic Plants	82
Aquiclude, Aquitard, Aquifuge	82
Aquifer	83
Aromatic Hydrocarbons	84
Arsenic and Selenium	84
Asabe Standard X593	85
Ash	85
Ash Analysis	86
Ash Composition	86
Ash Content	87
Ash Content – Biomass	89
As-Received Moisture	90
Atmosphere	90
Atmospheric Equivalent Boiling Point	94
Atomic Energy	94
Attapulgius Clay	95
Attrition Catalyst	95
Azeotrope	95
Azeotropic Distillation	96

B	99
Bacteria	99
Bacterial Mining	99
Bagasse	100
Bagasse Briquettes	101
Baghouse	101
Baghouse Filter	102
Barrel	102
Barrel of Oil Equivalent	103
Basic Nitrogen	103
Basic Sediment and Water	104
Batch-Type Processes	105
Baumé Gravity	105
Bauxite	106
Bauxite Treating Process	107
Beavon Process	107
Benchmark Crude Oil	107
Beta Decay	108
Beta Particle	109
Bioalcohol	109
Biocatalysts	111
Biochar	111
Biochemical Conversion	112
Biochemical Oxygen Demand	113
Biochemicals	113
Biochemicals - Production	114
Bioconversion	120
Bioconversion Platform	121
Biodegradation	122
Biodegradation – In Situ	124
Biodegradation Processes	125

Biodegradation – Slurry Phase	127
Biodegradation – Solid Phase	127
BioDeNOx Process	128
Biodesulfurization	128
Biodiesel	129
Biodiesel Feedstocks	131
Biodiesel – Production and Properties	133
Biodiesel – Technical Standards	135
Biodiesel – Transesterification	137
Biodiesel – Transesterification, Catalytic	138
Biodiesel – Transesterification, Supercritical Methanol	139
Biodiesel – Transesterification, Reaction Parameters	139
Bioenergy	140
Bioenergy Crops	140
Bioenergy System	141
Bioethanol	141
Bioethanol Production	142
Bioethers	142
Biofiltration	143
Biofuels	144
Biofuels - Classification	146
Biofuels - Feedstocks	148
Biofuels – First Generation	149
Biofuels – From Synthesis Gas	149
Biofuels – Liquid	150
Biofuels – Platforms	151
Biofuels – Production	152
Biofuels – Properties, Variations with Source	152
Biofuels – Second Generation	155
Biofuels – Specifications and Performance	156
Biofuels – Third Generation	157
Biofuels – Use	158
Biogas	158
Biogas – Upgrading	160
Biogenic Coal Bed Methane	162
Biogeochemical Cycles	162
Biohydrogen	163
Biohydrogen – Production	164
Biological Action	164
Biological Alcohol	165
Biological Conversion	165
Biological Conversion – Aerobic Digestion	165
Biological Conversion – Anaerobic Digestion	166
Biological Hydrogen Production	169
Biomass	169
Biomass Ash	172
Biomass Chemistry	172
Biomass Combustion	174
Biomass Composition and Properties	174
Biomass – Conversion Technologies	176
Biomass-Derived Carbon	177

Biomass – Direct Combustion	178
Biomass – Drying	178
Biomass Energy	180
Biomass Energy Systems	181
Biomass – Extraction	182
Biomass Feedstocks	182
Biomass – Fermentation	183
Biomass Fuel	183
Biomass Fuel – Characteristics	184
Biomass – Gasification	184
Biomass – Gasification Principles	186
Biomass – Gasification Process	186
Biomass – Gasification Reactors	187
Biomass – Herbaceous	189
Biomass – Land Requirements	190
Biomass – Liquefaction	191
Biomass Power	191
Biomass – Power Facility	191
Biomass Properties	192
Biomass – Pyrolysis	192
Biomass – Synthesis Gas Production	193
Biomass to Energy	195
Biomass to Liquids	196
Biomass Waste	198
Bio-oil	200
Bio-oil – Upgrading	202
Bio-oxidation	202
Biophotolysis	203
Biopower	203
Bioprocess	204
Bioreactor	205
Biorefinery	206
Bio-SCOT Process	209
Bioscrubbing	209
Bitumen	209
Black Liquor	210
Blended Fuels	211
Blending	211
Blue Gas	212
Blue Water Gas	212
Boiler Slag	212
Boiling Water Reactor	213
Bone Dry	213
Boson	213
Bottom Ash	213
Bottoming Cycle	214
Bottom Sediment and Water	214
Boudouard Reaction	214
Breeder Reactor	215
BRI Process	215
Briquette	215

Briquette Binder	216
Briquette Manufacture	217
Briquette Properties	217
Briquetting Processes	218
Bromine Number	219
BTEX	219
BTU	220
BTX	220
Bubble Point	220
Bubbling Fluidized Bed Gasifier	221
Bulk Density	221
Bunker	222
Bunker Fuel Oil	222
Butane	222
Butane Dehydrogenation	223
Butane Vapor-Phase Isomerization	224
Butanol	224
Butene	225
Butene Dehydrogenation	225

C	227
C ₁ , C ₂ , C ₃ , C ₄ , C ₅ Fractions	227
Calorific Value	227
Camelina	227
Canola Oil	228
Capillary Forces	228
Capillary Number	229
Capillary Pressure	229
Carbohydrates	229
Carbonate Washing and Water Washing	230
Carbonate Washing Process	230
Carbon Cycle	231
Carbon Dioxide	231
Carbon Dioxide Balance	231
Carbon Dioxide Gasification	232
Carbon Dioxide Recovery	232
Carbonization	233
Carbon Monoxide	234
Carbon Residue	234
Carbon Sink	234
Carbo-V Process	235
Carbureted Blue Gas	236
Carbureted Water Gas	236
Catalysts	236
Catalysts – Activity	237
Catalyst – Deactivation	238
Catalyst Fouling	238
Catalysts – Hydrogen Production	239
Catalysts – Methanation	240
Catalyst Poisoning	241
Catalyst Regeneration	241

Catalysts – Selectivity and Conversion	242
Catalyst Sintering	242
Catalysts – Solid Acid	242
Catalyst Stripping	243
Catalytic Cracking	243
Catalytic Cracking Chemistry	245
Catalytic Cracking Processes	246
Catalytic Cracking – Process Parameters	247
Catalytic Gas Conversion Process	249
Catalytic Gasification	249
Catalytic Oxidation Processes	250
Catalytic Reforming	251
Catalytic Reforming - Catalysts	252
Catalytic Reforming – Processes	253
Catalytic Three-Phase Reactors	254
Catalytic Transesterification	254
Caustic Scrubbing	255
Caustic Treating	255
Cellulose	256
Cellulosic Biomass	258
Cellulosic Ethanol	259
Cellulosic Materials	260
Centrifugal Separation	260
Cetane Index	261
Cetane Number	261
Char	262
Charcoal and Charcoal Briquettes	262
Chemical Composition of Biomass	264
Chemical Precipitation	265
Chemical Reaction Rates	266
Chemicals Reactive with Water	266
Chemical Treating	267
Chemical Waste	268
Chemicals from Biomass	268
Chemisorption	270
Chemistry in the Aquasphere	271
Chemistry in the Atmosphere	272
Chemistry in the Geosphere	274
Chemsweet Process	275
Chinese Tallow Tree	276
Circulating Fluidized Bed Gasifier	276
Claus Process	276
Clay Minerals	278
Clay Treating Process	279
Climate Change	279
Closed-Loop Biomass	281
Coagulation	281
Coarse Materials	282
Co-Combustion	282
COED/COGAS Process	282
Co-Firing	283

Cogeneration	283
Cohesive Energy Density	284
Cold Pelletizing	284
Combustion	284
Combustion - Chemistry	285
Combustion – Direct	287
Combustion – Effect of Additives and Catalysts	288
Combustion – Environmental Aspects	289
Combustion – Fluidized Bed	292
Combustion – Fouling	292
Combustion – Heat Balance	293
Combustion – Ignition	294
Combustion – Influence of Feedstock Quality	294
Combustion – Mechanism	294
Combustion – Soot Formation	295
Combustion – Surface Effects	296
Combustion Technologies	296
Combustion – Types of Combustors	298
Combustion Zone	300
Combustion Plants	300
Complete Mix Digester	302
Concentrated Acid Hydrolysis	302
Condensation	303
Coniferyl Alcohol	303
Conservation	304
Conservation Reserve Program	304
Contaminant	304
Contingent Resources	304
Conventional Fuel Sources	305
Conversion Pathways	306
Conversion Processes – Biochemical	306
Conversion Processes – Biomass Properties	307
Conversion Processes – Combustion	308
Conversion Processes – Gasification	309
Conversion Processes - Pyrolysis	310
Conversion Processes – Thermal	311
Copper Sweetening Process	312
Cord	312
Cordgrass	313
Coriolis Force	313
Corn	314
Corn Ethanol	314
Corn Oil	315
Corn Stalks and Wheat Straw	315
Corn-to-Ethanol Process	315
Corrosion	316
Corrosion by Fuel Ash	316
p-Coumaryl Alcohol	317
Counter-Current Fixed Bed Gasifier	317
Covered Lagoon Digester	317
Cracking	318

Cropland	319
Crops	319
Crops – Residues	321
Cross Draft Gasifier	321
Crude Oil	322
Cryogenic Dehydration	322
Cryogenic Equipment	322
Cryogenic Expander Process	323
Cryogenic Separation	323
Cryosphere	323
Crystallization	324
CTSL Process	324
Cull Tree	325
Cultivated Summer Fallow	325
Current Reserves	325
Cyclone Separation	326
Cycloparaffin Hydrocarbons	326

D	329
Darcy's Law	329
DEA	329
Dehydration	330
Dehydration – Glycol Process	330
Dehydration – Solid Desiccant	331
Dehydrator Systems	332
Delignification	333
Densification	333
Deposition	334
Descending Bed Reactor	335
Desiccant Dehydrators	335
Desorption	335
Deuterium	336
Devolatilization	337
Dewatering	337
Diesel-Alcohol Emulsion	340
Diesel Cycle	340
Diesel Engine	341
Diesel Fuel	341
Diesel Index	342
Digester	342
Digestion	344
Dimethyl Ether	344
Direct Biofuels	345
Direct Combustion	345
Direct-Fired Biomass	346
Dispersion	347
Dissolution	348
Distillation	349
Distribution in the Environment	351
Domestic Waste	355
Downdraft Combustion	356

Downdraft Gasifier	357
Downflow Fixed Bed Reactor	357
Drizo Process	358
Drop Tube Furnace	359
Dry-Ash-Free Basis	359
Dry Deposition	359
Drying	360
Dry Point	361
Dry Sorption Processes	362
Dust Collectors	362
Dust Control	363
Dustiness Index	363
Dutch Oven Furnace	364
E	365
E85	365
Earth System	365
Ebullated Bed Reactor	366
Ecological Cycles	366
Ecosystem	368
E-Gas Process	369
Electrical Energy	369
Electricity Generation – Equipment	369
Electricity Generation from Conventional Fuels	370
Electricity Generation from Crops	370
Electricity Generation from Waste	371
Electricity Generation from Wood	371
Electricity Generator	371
Electrochemical Processes	372
Electrolysis	372
Electron	373
Electronic Waste	373
Electrostatic Precipitator	374
Emissions and Effluents	375
Emission Control	380
Emulsification	381
Emulsifying Agents	382
Endothermic Reaction	383
Energy	383
Energy Balance	384
Energy Conservation	384
Energy Content	385
Energy Crops	385
Energy Crops – Grasses	388
Energy Crops – Oilseed Crops	389
Energy Crops – Residual Herbaceous Biomass	389
Energy Crops – Short Rotation Woody Crops	390
Energy Crops – Sugar Crops	390
Energy Density	391
Energy-Efficiency Ratio	391
Energy Production from Crops	392

Energy Production from Wood	397
Energy Sources	398
Enersludge Process	400
Enrichment	400
Entrained-Bed Combustion	401
Entrained-Bed Gasifier	401
Entrained-Flow Process	402
Entrained Flow Reactor	402
Environment	402
Environmental Ethics	403
Environmental Issues	403
Environmental Issues – Biomass Use	405
Enzymatic Hydrolysis	406
Enzymes	407
Esterification	408
Ethanol	409
Ethanol Production	411
Ethanol Production – Feedstocks	412
Ethanol Production – From Corn	413
Ethanol Production – From Lignocellulosic Feedstocks	414
Ethanol Production – From Wood	415
Ethanol Production - Yields	415
Ethyl Alcohol	416
Evaporation	416
Evaporation Processes	418
Exosphere	418
Exothermic Reaction	419
Explosive Limits	419
Extraction	420
Extractive Distillation	420
Explosive Limits	421
Extra Heavy Crude Oil	421
Extraneous Mineral Matter	422
ExxonMobil AGC-21 Process	422
F	423
Fabric Filter	423

Fischer-Tropsch Process	435
Fischer-Tropsch Process – Catalysts	436
Fischer-Tropsch Chemicals	436
Fischer-Tropsch Process	437
Fischer-Tropsch Process – Chemistry	439
Fischer-Tropsch Process – Commercial Processes	440
Fischer-Tropsch Process – Products	442
Fischer-Tropsch Process – Product Separation and Upgrading	443
Fischer-Tropsch Process – Reactors	444
Fixed-Bed Incinerator or Moving-Grate Incinerator	444
Fish Oil	445
Fixed-Bed Process	445
Fixed-Bed Reactor or Moving-Bed Reactor	446
Fixed Carbon	446
Flammability	446
Flammability Range	448
Flash Point	448
Flash Pyrolysis	449
Flash Vaporization	450
Flax and Flaxseed Oil	450
Flexible-Fuel Vehicle	451
Flexsorb Process	451
Flocculation	452
Flue Gas	452
Flue Gas Cleaning	454
Flue Gas Desulfurization	454
Fluid Bed	455
Fluid-Bed Boiler	456
Fluid-Bed Catalytic Cracking	456
Fluid-Bed Catalytic Cracking Unit	457
Fluid-Bed Combustion	457
Fluid-Bed Gasifier	459
Fluid-Bed Incinerator	459
Fluid-Bed Processes	460
Fluid-Bed Reactor	460
Fluid-Bed Thermal Cracking	461
Fly Ash	461
Forage Crop	462
Forest Health	462
Forest Land	462
Forest Residues	463
Fossil Fuel Resources	463
Fouling	464
Fouling Tendency	464
Fractional Composition	466
Fractionation	466
Fractionation – Absorption Methods	467
Fractionation – Adsorption Methods	468

Fractionation – Chemical Methods	468
Fractionation – Distillation Methods	468
Fractionation – Solvent Methods	469
Fuel Cell	470
Fuel Oil	470
Fuels	471
Fuels from Biomass	471
Fuels from Crops	472
Fuels from Waste	473
Fuels from Wood	474
Fuel Wood	475
Fuel Wood – Selection and Preparation	476
Fuel Wood – Use	476
Functional Group	477
Fungi	479
Fusion Energy	480
G	481
Gamma Decay	481
Gas Analysis	481
Gas Cleaning	483
Gas Cleaning – Alkali Washing Processes	485
Gas Cleaning – Biological Methods	485
Gas Cleaning – Chemisorption	486
Gas Cleaning – Effects of Gas Composition	489
Gas Cleaning – Membrane Processes	490
Gas Cleaning – Metal Oxide Processes	491
Gas Cleaning – Methanol Based Processes	491
Gas Cleaning – Molecular Sieve Processes	492
Gas Cleaning – Physical Solvent Processes	493
Gas Cleaning – Process Selection	494
Gas Cleaning – Process Types	495
Gas Cleaning – Removal of Acid Gases	496
Gas Cleaning – Removal of Alkali Metal Salts	504
Gas Cleaning – Removal of Ammonia	504
Gas Cleaning – Removal of Condensable Hydrocarbons	504
Gas Cleaning – Removal of Nitrogen	508
Gas Cleaning – Removal of Particulate Matter	509
Gas Cleaning – Removal of Siloxane Derivatives	509
Gas Cleaning – Removal of Tar	510
Gas Cleaning – Sulfur Recovery Processes	511
Gas Cleaning – Water Removal	512
Gas Compression	515
Gas Condensate	516
Gas-Cooled Reactor	516

Introduction

Energy (from whatever the sources – fossil fuel sources or renewable sources, often referred to as alternate sources) appears in many different forms, including electricity, light, heat, chemical energy, and motional (or kinetic) energy. An important scientific discovery in the 19th century was that energy is conserved, which means that energy can be converted from one form to another but that the total amount of energy must stay the same.

Renewable energy can be derived from a variety of sources because the sources can be used and replaced without irreversibly depleting reserves or the sources (such as power from water systems, wind systems, and the sun) are consistently present in the Earth system, which makes these sources a valuable resource for the consistent production of energy. For this reason, renewable sources will continue to grow in importance as replacements for fossil materials used as fuels and as feedstocks for a range of products. Some renewable materials also have particular unique and beneficial properties which can be exploited in a range of products including pharmaceuticals and lubricants.

The concept is centered around a long-term vision that a significant proportion of the demand for energy and raw materials should be met through the commercial exploitation of science from crops, in a way which stimulates biodiversity and reduces greenhouse gas emissions and waste – particularly biodegradable waste going to a landfill site – and slows depletion of finite natural resources.

Fuels based on natural gas and crude oil are well-established products that have served industrial and domestic consumers for more than a hundred years. For the foreseeable future most of these fuels will still be largely based on liquid hydrocarbon derivatives. The specifications of such fuels will, however, continue to be adjusted as they have been and are still being adjusted to meet changing demands from consumers. Traditional refining of natural gas and crude oil underwent increasing levels of sophistication to produce fuels of appropriate specifications. Increasing operating costs continuously put pressure on refining margins but it remains problematic to convert all refinery streams into products with acceptable specifications at a reasonable return.

However, time is running out and natural gas and crude oil, once considered inexhaustible, is now being depleted at a rapid rate – the gas and oil from tight formations notwithstanding. As the amount of available natural gas and crude oil decreases, the need for alternate technologies to produce liquid fuels that could potentially help prolong the liquid fuels culture and mitigate the forthcoming effects of the shortage of transportation fuels that has been suggested to occur under the Hubbert peak oil theory. To mitigate the influence of the oil peak and the subsequent depletion of supplies, unconventional (or non-gas and crude oil) fuels are becoming a major issue in the consciousness of oil-importing countries.

In the near term, the ability of conventional fuel sources and technologies to support the global demand for energy will depend on how efficiently the energy sector can match available energy resources with the end user and how efficiently and cost effectively the energy can be delivered. These factors are related to the continuing evolution of a truly global energy market. In the long term, a sustainable energy future cannot be created by treating energy as an independent topic (Zatzman, 2012). Rather, the role of the energy and the interrelationship of the energy market with other markets and the various aspects of market infrastructure demand further attention and consideration. Greater energy efficiency will depend on the developing world market's ability to integrate energy resources within a common structure.

However, the production of liquid fuels from sources other than natural gas crude oil (as well as coal and oil shale) has a checkered history. The on-again-off-again efforts that are the result of political maneuvering has seen to it that the race to secure self-sufficiency by the production of non-conventional fuels has never got much further than the starting gate! This is due in no small part to the price fluctuations in the price of natural gas and crude oil

accompanied by the lack of foresight by various levels of government. It must be realized that for decades the price of natural gas and crude oil (and the resulting fuel products) has always been maintained at a level that was sufficiently low to discourage the establishment of an alternate fuels industry. However, it is close to the time when the lack of preparedness for the production of non-conventional fuels may set any national government on its heels.

On the other hand, alternate fuels, such as gasoline and diesel fuel derived from non-fossil carbonaceous sources, are making headway into the fuel balance. For example, naphtha – the typical starting liquid for automotive fuels – and biodiesel from plant sources is similar to naphtha and kerosene but may have differences that include a different distribution of the constituents. At this time, the potential for liquid fuels from various types of biomass is also seeing considerable interest.

Whatever the source of the fuels (gaseous, liquid, or solid) there is always the need for methods by which the fuels can be analyzed and specification derived. Typically, this aspect of non-fossil fuel technology is often omitted from many of the relevant works. In order to combat and mitigate such omissions, this encyclopedia contains articles related to product analysis that includes general descriptions of and references to the relevant test methods.

In order to satisfy specific needs with regard to the type of feedstock to be processed, as well as to the nature of the product, the various standard test methods and specifications are a means of describing and/or recommending the rules and conditions for how materials and products should be manufactured, defined, measured, or tested. There are various standards organizations, such as the ASTM International (formerly known as American Society for Testing and Materials). Thus, it is appropriate that in any discussion of the physical properties of fuels from non-fossil fuel sources and, accordingly, where appropriate, the various ASTM test numbers have been cited in the text.

However, although not mentioned in the text, several other countries have standard test methods for fuel identification – examples are Germany (identified by the prefix DIN), the European countries (intended to be used in the European Union and identified by the prefix EN), the International Standards Organization (identified by the prefix ISO) and the United Kingdom (identified by the prefix IP and the prefix BS) – these test methods are not referenced in this encyclopedia but are available through the use of an internet search engine to which the reader is referred for further details and comparison of the test methods.

Following nomenclature and definitions presented in the United States Energy Policy Act of 1992 (Section 301), in the context of the present book, alternate fuels (alternative fuels) are defined as

Methanol, denatured ethanol, and other alcohols; mixtures containing 85 percent or more (or such other percentage, but not less than 70 percent, as determined by the Secretary, by rule, to provide for requirements relating to cold start, safety, or vehicle functions) by volume of methanol, denatured ethanol, and other alcohols with gasoline or other fuels; natural gas; liquefied petroleum gas; hydrogen; coal-derived liquid fuels; fuels (other than alcohol) derived from biological materials; electricity (including electricity from solar energy); and any other fuel the Secretary determines, by rule, is substantially not natural gas or crude oil and would yield substantial energy security benefits and substantial environmental benefits.

It is this definition that is used to guide the contents of this book and show that sources that are “*substantially not petroleum*” are available as sources of fuels.

However, it must be recognized that the forms of energy from renewable sources vary according to the source. For example, biomass and waste can be combusted directly or they can be converted to gaseous fuels and liquid fuels by conversion and refining of the gases and the liquids. The encyclopedia would be missing important articles if there was not some mention of the methods and processes by which gases and liquid products from renewable sources can be prepared for sales. Accordingly, the technologies for refining the gases and liquids into usable fuels and other (petrochemical-type) products are derived from the current natural gas industry and the crude oil industry. Hence the reason for inserting the relevant refining-related articles into the encyclopedia.

In addition, there is a fundamental attractiveness about harnessing such forces in an age which is very conscious of the environmental effects of burning fossil fuels, and where sustainability is an ethical norm. Currently, the focus of many countries is on both adequacy of energy supply long term and also the environmental implications of particular sources. In that regard the near certainty of costs being imposed on carbon dioxide emissions in developed countries at least has profoundly changed the economic outlook of clean energy sources.

However, there is the need to understand that all energy sources have some impact on the environment. Renewable energy sources do substantially less harm to the environment than do fossil fuels (coal, natural gas, and crude oil) by most measures, including air and water pollution, damage to public health, wildlife and habitat loss, water use, land use, and global warming emissions. However, renewables such as biomass as well as sources such as wind, solar, geothermal, and hydropower also have environmental impacts, some of which are significant and must not be ignored. This encyclopedia also presents information related to those aspects of environmental science and engineering that are susceptible to changes caused by renewable energy sources in addition to the environmental effects caused by the use of fossil fuels. It is for these reasons that articles related to the discharge of pollutants into the environment are included.

In fact, when the benefits of developing renewable energy sources are considered, it is equally important to acknowledge that there can also be disadvantages. While all renewable energy sources – wind, solar, geothermal, hydroelectric, and biomass – can provide substantial benefits for the climate and the economy, all energy sources have some impact on the environment and even renewable sources such as biomass, wind, solar, geothermal, biomass, and hydropower also have environmental impacts, some of which are significant. The exact type and intensity of environmental impacts varies depending on the specific technology used, the geographic location, and a number of other factors. By understanding the current and potential environmental issues associated with each renewable energy source, effective measures can be taken to avoid or minimize these impacts as they become a larger portion of the electric supply.

However, there is a variety of environmental impacts associated with the use of alternative energy sources which can include land use and habitat loss, water use that should be recognized and mitigated. They include land use issues and challenges to wildlife and habitat. The exact type and intensity of environmental impacts varies depending on the specific technology used, the geographic location, and a number of other factors. For example, sources of biomass resources for producing energy are diverse, ranging from energy crops (like switchgrass), to agricultural waste, manure, forest products and waste, and urban waste. Both the type of feedstock and the manner in which it is developed and harvested significantly affect land use and life-cycle global warming emissions impacts of producing power from biomass.

It must be realized that the transfer from non-renewable energy source to renewable energy sources is not without some risk. Just as chemicals from non-renewable energy sources can enter the environment, chemicals from renewable energy sources can also enter the air, water, and soil when they are produced, used, or disposed. The impact of these chemicals on the environment is determined by the amount of the chemical that is released, the type and concentration of the chemical, and where it is found. Some chemicals can be harmful if released to the environment even when there is not an immediate, visible impact. On the other hand, some chemicals are of concern as they can work their way into the food chain and accumulate and/or persist in the environment for many years.

The final concentration of a chemical (or a mixture of chemicals) in various environmental systems (such as the atmosphere, water, and the land) depends on environmental emission rates and environmental distribution and fate of the chemical. Thus the first step in environmental risk assessment is always to quantify the emissions of a chemical into the atmosphere, the water, and the land.

Many chemicals, in fact all chemicals, that enter the environment should be categorized and ranked using hazard assessment criteria. This would not only ensure that truly pressing environmental issues are identified and prioritized, but would also maximize the use of limited resources. In the case of soluble chemicals, surrogate data such as persistence and bioaccumulation have been used, in combination with toxicity, for the purpose of hazard categorization. However, for insoluble or sparingly soluble chemicals such as metals and metal compounds, persistence and bioaccumulation are neither appropriate nor useful. Unfortunately, this is not always recognized by regulators or even by scientists.

The use of persistent, bioaccumulative and toxic (PBT) criteria for chemicals was developed to address the hazards posed by synthetic organic chemicals. In fact, the criteria and test methods to evaluate persistence (i.e., the lack of degradability of a chemical) and bioaccumulation (the dispersion of a chemical through knowledge of the water-octanol partition coefficient) were developed to be used in combination with toxicity in order to reduce the importance given to the use of toxicity data alone. These test methods were based on an understanding of the chemistry of chemicals of concern at the time and of the biological interactions that the chemicals would have with the surrounding

biota. Specifically, it was realized that if some chemicals exerted high intrinsic toxicity under standardized laboratory test conditions but did not persist or bioaccumulate, the environmental hazard of such chemicals would be lower.

As mentioned above, persistence is measured by determining the lack of degradability of a substance from a form that is biologically available and active to a form that is less available. This applies to many substances – metals and metal compounds tend to be in forms that are not bioavailable. Only under specific conditions would metals or metal compounds transform into a bioavailable form. Thus, rather than persistence, the key criterion for classifying metals and metal compounds should be their capacity to transform into bioavailable form(s). Furthermore, although bioavailability is a necessary precursor to toxicity, it does not inevitably lead to toxicity. Although metals and metal compounds stay in the environment for long periods of time, the risk they may pose generally decreases over time. For example, metals introduced into the aquatic environment are subject to removal/immobilization processes (e.g., precipitation, complexation and absorption).

Similarly, the use of bioaccumulation has significant limitations for predicting hazard for metals and metal compounds. Generally, either bioconcentration factors (BCFs) or bioaccumulation factors (BAFs) are used for this purpose. A bioconcentration factor is the ratio of the concentration of a substance in an organism, following direct uptake from the surrounding environment (water), to the concentration of the same substance in the surrounding environment. A bioaccumulation factor considers uptake from food as well. In contrast to organic compounds, uptake of metals is not based on lipid partitioning. Further, organisms have internal mechanisms (homeostasis) that allow them to regulate (bioregulate) the uptake of essential metals and to control the presence of other metals. Thus, if the concentration of an essential metal in the surrounding environment is low and the organism requires more, it will actively accumulate that metal. This will result in an elevated bioconcentration factors (or bioaccumulation factor) value which, while of concern in the case of organic substances, is not an appropriate measure in the case of metals.

The primary determining factor of hazard for metals and metal compounds is therefore toxicity, which requires consideration of dose (indeed, the fundamental tenet of toxicology is *the dose makes the poison*). Historically, it has been the practice to measure the toxicity of soluble metal salts, or indeed the toxicity of the free metal ion. However, in different media, metal ions compete with different types or forms of organic matter (e.g., fish gills, suspended solids, soil particulate material) to reduce the total amount of metals present in bioavailable form. Toxicity of the bioavailable fraction (i.e., as determined through transformation processes) is the most appropriate and technically defensible method for categorizing and ranking the hazard of metals and metal compounds.

The relative proportion of hazardous constituents present in any collection of chemicals (crude oil-derived products included) is variable and rarely consistent because of site differences. Therefore, the extent of the contamination will vary from one site to another and, in addition, the farther a contaminant progresses from low molecular weight to high molecular weight the greater the occurrence of polynuclear aromatic hydrocarbons, complex ring systems (not necessarily aromatic ring systems) as well as an increase in the composition of the semi-volatile chemicals or the non-volatile chemicals. These latter chemical constituents (many of which are not so immediately toxic as the volatiles) can result in long-term/chronic impacts to the flora and fauna of the environment. Thus, any complex mixture of chemicals should be analyzed for the semi-volatile compounds which may pose the greatest long-term risk to the environment.

Heavy metals are common chemical pollutants. The most common heavy metals found at contaminated sites, in order of abundance are Pb, Cr, As, Zn, Cd, Cu, and Hg. Those metals are important since they are capable of decreasing crop production due to the risk of bioaccumulation and biomagnification in the food chain. There is also the risk of superficial and groundwater contamination. Knowledge of the basic chemistry, environmental, and associated health effects of these heavy metals is necessary in understanding their speciation, bioavailability, and remedial options. The fate and transport of a heavy metal in soil depends significantly on the chemical form and speciation of the metal. Once in the soil, heavy metals are adsorbed by initial fast reactions (minutes, hours), followed by slow adsorption reactions (days, years) and are, therefore, redistributed into different chemical forms with varying bioavailability, mobility, and toxicity (Shiowatana et al., 2001). This distribution is believed to be controlled by reactions of heavy metals in soils such as (i) mineral precipitation and dissolution, (ii) ion exchange, adsorption, and desorption, (iii) aqueous complexation, (iv) biological immobilization and mobilization, and (v) plant uptake (Levy et al., 1992). The toxicity of metals varies greatly with pH, water hardness, dissolved oxygen levels, salinity, temperature and other parameters.

The specific type of metal contamination found in a contaminated soil is related to the operation that occurred at the site. The range of contaminant concentrations and the physical and chemical forms of contaminants will also depend on activities and disposal patterns for contaminated wastes on the site. Other factors that may influence the form, concentration, and distribution of metal contaminants include soil and groundwater chemistry and local transport mechanisms.

Finally, in order to evaluate the impact of a chemical that has been released to the environment, the chemical must be characterized in terms of the transport and transformation in that system (atmosphere, water, or land) and the potential for the transport of the chemical from one system to another or from one system to the other two. The assessment should focus on areas with which a released chemical is most likely to have contact. For a meaningful characterization, the environment must be viewed as a series of interacting compartments and it must be determined whether a chemical will remain and accumulate in the local area of the origin of the chemical. The potential for the chemical to be physically, chemically, or biologically transformed in the system of its origin (such as by hydrolysis, oxidation, or other transformation; Chapter 8) or be transported to another system such as by volatilization or by precipitation. The chemical could also be transferred by deposition and runoff to surface water that provides drinking water.

Each of these scenarios defines a pathway from the air emission to contact with a person, and each pathway has an associated route of contact. The true potential for exposure cannot be quantified until the pathways and routes that account for a substantial fraction of the intake and uptake for the receptor population have been identified. The likelihood of any pathway depends on the chemical properties of the substance released, where and how it is released, and environmental conditions. Sometimes the exposure increases along a pathway (such as bioaccumulation), but more often the exposure may decrease.

Thus, characterizing transportation pathways begins at the source of the agent release. In some situations, the source may be obvious and can be defined and characterized from air or soil concentrations. In many cases, such as contamination of water supplies, sources and emissions may be multiple and poorly characterized. However, classification of a potential transportation route should, as much as possible, be based on the released volume, duration of the release, and the rate of emission.

In order to fully understand the impact of a released chemical on the environment, the potential for chemical transformation of the spilled chemical which may occur as a result of biotic or abiotic processes, can significantly reduce the concentration of a substance or alter its structure in such a way as to enhance or diminish its toxicity or change its toxic effect. For example, for many airborne organic compounds, transformation processes, such as photolytic decomposition and oxidation/reduction reactions, can result in conversion to other compounds. For organic chemicals, the half-life of the chemical for any given transformation process provides a useful index of persistence in environmental media. For example, the photochemical half-life can vary from day to night, and specific information on the rates and pathways of transformation for individual chemicals of concern must be obtained directly from experimental determinations or derived indirectly from information on chemicals that are structurally similar to the released chemical.

Despite these environmental impacts, renewable energy technologies compare extremely favorably to fossil fuels, and remain a core part of the solution to future energy requirements. Renewable energy is going to be an important source for power generation in the near future because the resources again and again produce useful energy. Wind power generation is considered as having lowest water consumption, lowest relative greenhouse gas emission, and most favorable social impacts. It is considered as one of the most sustainable renewable energy sources, followed by hydropower, photovoltaic, and then geothermal. As these resources are considered as clean energy resources, they can be helpful for the mitigation of greenhouse effect and global warming effect.

However, by understanding the components of the environment and the current and potential environmental issues associated with each renewable energy source, the reader can understand the means to effectively avoid or minimize these impacts as they become a larger portion of energy supply. For this reason, this encyclopedia is an all-inclusive work that also presents not only the environmental components but also the various environmental aspects of the generation and use of renewable energy. Other issues arise that are similar to those produced by the use of fossil fuels – contamination of the atmosphere, water, and the land – but the degree of the contamination is not the same.

However, it would be a serious omission if recognition of some of the potential properties and effects of renewable fuels such as biogas and bio-oil and were omitted from this work. For example, biogas and bio-oil could cause harm

to the environment is used without any form of treatment. The gas needs to be cleaned of objectionable environmentally harmful constituents and the bio-oil (from whatever the source) needs to be processed to provide useable products. Accordingly, it has been necessary to include options for gas cleaning and options for bio-oil refining (such as hydrotreating and hydrocracking) so that the reader may understand the conditioning of these products into environmentally benign use.

The dynamics are now coming into place for the establishment of an alternate energy industry and it is up to various levels of government not only to promote the establishment of such an industry but to lead the way, recognizing that it is not only supply and demand but the available and variable technology. The processes for recovery of the raw materials and the processing options have changed in an attempt to increase the efficiency of energy production.

In addition, there are several interrelationships between conventional fuels and alternate fuels, especially in the areas of fuel production and fuel refining. Accordingly, it has been found necessary to include segments for the conventional fuel industries that are applicable to the alternate fuels industries. As ready reference, the articles in this encyclopedia have been assembled to assist the reader to understand the options that are available for the production of alternate energy, especially alternate fuels, and such processes from the conventional fuels industries and also from the unconventional fuels are, where they are applicable to renewable fuels, also included.

The Scrivener Encyclopedia of Renewable Energy was compiled because the need was recognized for an extensive work on the nature of renewable energy sources. This will be a convenient-to-use encyclopedia that will be a suitable companion for the researcher, teacher, and manager. Also, in order for help the reader understand the nature of renewable energy sources (Table 1), the encyclopedia contains segments that will allow the reader to compare renewable energy sources with the (to date) more conventional fossil fuels resources and how the conventional processing units that will be necessary to process renewable energy sources that are in the form of gases, liquid and solid.

Table 1 Simplified categorization and nomenclature of the various energy sources.

<i>Conventional Energy Sources</i> Natural gas Crude oil Heavy crude oil Coal*
<i>Non-conventional Energy Sources</i> Extra heavy crude oil Tar sand bitumen Coal* Coal gas Coal liquids Shale oil
<i>Renewable Energy Sources</i> Biomass Waste Hydrogen Hydroelectric energy** Geothermal energy Nuclear energy Ocean Energy** Solar energy Tidal energy** Wind energy

*When used as a solid fuel for combustion processes and without any modification other than cleaning, coal is often considered to be a conventional energy source.

**Often grouped together under the name “hydrokinetic energy” – hydroelectric energy may also be included in this group.

The encyclopedia also contains a section on further reading for those readers who require further information on any of the subjects.

Finally, the temperature scales used in this work are the Centigrade (Celsius) scale and the Fahrenheit scale. Generally, when the temperature is below 100°C the conversion to the exact temperature in degrees Fahrenheit is presented immediately following in parenthesis. On the other hand, when the temperature is above 100°C the conversion to the nearest 5° Fahrenheit is presented immediately following in parenthesis.

Absorption

When gaseous products are produced from a source, the gas stream will invariably contain unwanted constituents that must be removed. This not only applies to natural gas streams and gas streams produced during the refining of the crude oil (as well as to gas streams produced from the other fossil fuels) but also to the alternative fuel industry where gas streams are produced from feedstocks such as biomass and waste. One such process for removing the unwanted constituents is the absorption process.

Absorption is a physical or chemical process by which molecules enter a liquid or solid bulk phase and is different to adsorption in which a chemical is subject to the surface forces of the adsorbent (Table A-1).

Table A-1 Examples of the types of absorption.

Solute*	Absorbent	Absorption type
Ammonia	Water	Physical
Carbon dioxide	Ethanolamine	Chemical, reversible
Carbon dioxide	Sodium hydroxide (aq.)	Chemical, irreversible
Hydrochloric acid	Sodium hydroxide (aq.)	Chemical, irreversible
Hydrochloric acid	Water	Physical
Hydrogen sulfide	Sodium hydroxide (aq.)	Chemical, irreversible
Hydrogen sulfide	Olamine**	Chemical, reversible
Nitrogen oxides	Water	Chemical, reversible
Sulfur dioxide	Water	Physical and chemical***

*Listed alphabetically by solute.

**For example, monoethanolamine and diethanolamine.

***In addition to dissolution (physical absorption), there is also the potential for chemical absorption by the occurrence of the reversible reaction: $\text{SO}_2 + \text{H}_2\text{O} \leftrightarrow \text{H}_2\text{SO}_3$

Absorption is the process by which a gas is distributed throughout an absorbent (liquid); depends only on physical solubility and may include chemical reactions in the liquid phase (chemisorption). The process is generally used to separate a higher-boiling constituent from other components of a system of vapors and gases. The absorption medium is usually an oil in the range of gas oil. Absorption is widely employed in the gas clearing (gads processing) industry for recovery or removal of constituents from natural gas stream and from cured oil refinery streams of natural gasoline from well gas and of vapors given off by storage tanks. The reverse of this, i.e., the transfer of the absorbed constituents (the stripping process) is accomplished by contacting the absorbent (liquid or solid) liquid with an inert gas such as nitrogen or steam. With aqueous waste streams the stripping gas is usually air.

Scrubbing is primarily concerned with the removal of particulate liquids or solids from gas streams by contacting the gas with a liquid scrubbing medium. That is, the particles are scrubbed out of the gas. However, if the gas also contains some soluble gaseous components, they can dissolve in the scrubber solution. Thus, the scrubber may also be an absorber, just as an absorber may also be a scrubber if the feed contains particulate matter as well as soluble components. Absorption and scrubbing are commonly used separation processes for preventing air pollution from industrial exhaust or stack gases. Stripping is used for both prevention of water pollution by treatment of wastewaters to remove soluble toxic gases and remediation of contaminated water at already existing hazardous waste sites.

Typically, absorption is achieved by dissolution (a physical phenomenon) or by reaction (a chemical phenomenon) and is different from adsorption (Table A-2).

Table A-2 Comparison of adsorption and absorption.

	Adsorption	Absorption
Definition	Accumulation at the surface the solid or liquid	Accumulation in the bulk of solid or liquid
Characteristic	A surface phenomenon	A bulk phenomenon
Concentration	Different at surface to bulk	Same throughout
Reaction rate	Increases to equilibrium	Occurs at a uniform rate
Reaction type	Exothermic process	Endothermic process
Temperature	Unaffected by temperature	Not affected by temperature

Chemical adsorption processes adsorb sulfur dioxide onto a carbon surface where it is oxidized (by oxygen in the flue gas) and absorbs moisture to give sulfuric acid impregnated into and on the adsorbent.

Liquid absorption processes (which usually employ temperatures below 50°C (120°F) are classified either as physical solvent processes or chemical solvent processes. The former processes employ an organic solvent, and low temperatures, or high pressure, or both enhance absorption; regeneration of the solvent is often accomplished readily. In chemical solvent processes, absorption of the acid gases is achieved mainly by use of alkaline solutions such as amines or carbonates. Regeneration (desorption) can be achieved by the use of reduced pressures and/or high temperatures, whereby the acid gases are stripped from the solvent.

If absorption is a physical process not accompanied by any other physical or chemical process, it usually follows the Nernst partition law in which the ratio of concentrations of solute species in two bulk phases in contact is constant for a given solute and bulk phases, i.e.:

$$X_1/X_2 = \text{constants} = K_{N(X\ 1,2)}$$

The value of constant K_N , the *partition coefficient*, is dependent upon temperature and the value is valid if concentrations are not too large and if the species x does not change its chemical or physical form in either phase-1 or phase-2.

In the case of gas absorption, the concentration a solute (c) in one of the phases can be calculated using the *Ideal gas law* (e.g., $c = p/RT$). Alternatively, partial pressure may be used instead of concentration.

The absorption oil has an affinity for the natural gasoline constituents. As the gas stream is passed through an absorption tower, it is brought into contact with the (lean) absorption oil which soaks up a high proportion of the liquid hydrocarbons. The rich absorption oil now containing the hydrocarbons exits the absorption tower through the base after which it is fed into lean oil stills, where the mixture is heated to a temperature above the boiling point of the absorbed hydrocarbons but below that of the oil. This process allows for the recovery of approximately 75% v/v of butanes, and 85 to 90% v/v percent of pentanes and higher boiling hydrocarbons from the stream.

The process above can be modified to improve its effectiveness, or to target the extraction of specific hydrocarbons. In the refrigerated oil absorption method, where the lean oil is cooled through refrigeration, propane recovery can be upwards of 90% v/v and around 40% v/v of any of ethane present in the gas stream. Extraction of higher molecular weight hydrocarbons approaches 100% v/v using this process.

Absorption Cleaning

Absorption is an approach in which the absorbed gas is ultimately distributed throughout the absorbent (liquid). Gas absorption (sometimes also known as gas scrubbing) is an operation in which a gas mixture is contacted with a

liquid for the purpose of preferentially dissolving one or more components of the gas mixture and to provide a solution of the components in the liquid phase. When water and hydrocarbon oils are used as absorbents, no significant chemical reactions occur between the absorbent and the solute, and the process is commonly referred to as physical absorption.

The process involves a mass transfer of the component of the gas from the gas phase to the liquid phase in which the solute so transferred is absorbed by the liquid. In gas desorption (also known as stripping), the mass transfer is in the opposite direction, i.e., from the liquid phase to the gas phase. Typically, there is no chemical reaction involved in the absorption process and it operates under isothermal conditions. Common absorbing media used are water, aqueous amine solutions, caustic, sodium carbonate, and nonvolatile hydrocarbon oils, depending on the type of gas to be absorbed. Usually, the gas-liquid contactor designs which are employed are plate columns or packed beds.

Chemical adsorption processes adsorb sulfur dioxide onto a carbon surface where it is oxidized (by oxygen in the flue gas) and absorbs moisture to give sulfuric acid impregnated into and on the adsorbent. When aqueous sodium hydroxide (a strong base) is used as the absorbent to dissolve an acid gas, absorption is accompanied by a rapid and irreversible neutralization reaction in the liquid phase and the process is referred to as chemical absorption or reactive absorption.

More complex examples of chemical absorption are processes for acid gas removal from gas streams. In the process, carbon dioxide (CO_2) and hydrogen sulfide (H_2S) are absorbed by treating the gas stream (invariably by passing the gas stream through the liquid absorbent) with an aqueous solution of monoethanolamine (MEA), diethanolamine (DEA), diethylene glycol (DEG) or triethylene glycol (TEG), where a reversible chemical reaction takes place in the liquid phase. Chemical reactions can increase the rate of absorption, increase the absorption capacity of the solvent, increase selectivity to preferentially dissolve only certain components of the gas, and convert a hazardous chemical to a safe compound.

Absorption Dehydration

An example of absorption dehydration is known as *glycol dehydration* and diethylene glycol, the principal agent in this process, has a chemical affinity for water and removes water from the gas stream. In this process, a liquid desiccant dehydrator serves to absorb water vapor from the gas stream.

Essentially, glycol dehydration involves using a glycol solution, usually either diethylene glycol (DEG) or triethylene glycol (TEG), which is brought into contact with the wet gas stream in a *contactor*. The glycol solution will absorb water from the wet gas and once absorbed, the glycol particles become heavier and sink to the bottom of the contactor where they are removed. The gas stream, having been stripped of most of its water content, is then transported out of the dehydrator. The glycol solution, bearing all of the water stripped from the gas stream, is put through a specialized boiler designed to vaporize only the water out of the solution. The boiling point differential between water (100°C , 212°F) and glycol (204°C , 400°F) makes it relatively easy to remove water from the glycol solution, allowing it to be reused in the dehydration process.

As well as absorbing water from the wet gas stream, the glycol solution occasionally carries with it small amounts of methane and other compounds found in the wet gas. In the past, this methane was simply vented out of the boiler. In addition to losing a portion of the gas stream that was extracted, this venting contributes to air pollution and the greenhouse effect. In order to decrease the amount of methane and other compounds that are lost, flash tank separator-condensers work to remove these compounds before the glycol solution reaches the boiler. Essentially, a flash tank separator consists of a device that reduces the pressure of the glycol solution stream, allowing the methane and other hydrocarbons to vaporize (*flash*).

The glycol solution then travels to the boiler, which may also be fitted with air or water cooled condensers, which serve to capture any remaining organic compounds that may remain in the glycol solution. The regeneration (stripping) of the glycol is limited by temperature: diethylene glycol and triethylene glycol decompose at or before their respective boiling points. Such techniques as stripping of hot triethylene glycol with dry gas (e.g., heavy hydrocarbon vapors, the *Drizo process*) or vacuum distillation are recommended.

In practice, absorption systems recover 90 to 99% by volume of methane that would otherwise be flared into the atmosphere.

See also: Absorption, Gas Cleaning, Gas Processing, Gas Treating.

Absorption Oil

Absorption oil (also called absorber oil, scrubbing oil, wash oil) is low-boiling liquid hydrocarbon used to absorb or remove the higher-boiling liquid hydrocarbons from a gas stream. Typically, absorption oil is a hydrocarbon-based liquid that is contacted with a gas stream to remove higher boiling components, such as occurs in the recovery of natural gasoline from the gas stream (often referred to as the wet gas stream).

An absorption plant is a facility used to recover the condensable portion of the gas stream to remove acid gas stream. Typically, the absorption takes place in a counter-flow (countercurrent) vessel, where the gas stream enters the bottom of the vessel and flows upward through the absorption oil. The plant also includes the necessary ancillary thermal units to distill the absorbed hydrocarbons from the higher boiling absorption oil.

See also: Absorption, Absorption Processes, Gas Cleaning, Gas Processing, Gas Treating, Olamine Processes.

Absorption Process

The absorption method of extraction is similar to using absorption for dehydration. The main difference is that in the absorption of liquids from the gas stream, absorbing oil is used as opposed to glycol. This absorbing oil has an affinity for gas liquids in much the same manner as glycol has an affinity for water. Before the oil has picked up any gas stream liquids, it is termed lean absorption oil.

The oil absorption process involves the countercurrent contact of the lean (or stripped) oil with the incoming wet gas with the temperature and pressure conditions programmed to maximize the dissolution of the liquefiable components in the oil. The rich absorption oil (sometimes referred to as fat oil), containing gas liquids, exits the absorption tower through the bottom. It is now a mixture of absorption oil, propane, butanes, pentanes, and other higher-boiling hydrocarbons. The rich oil is fed into lean oil stills, where the mixture is heated to a temperature above the boiling point of the gas liquids but below that of the oil. This process allows for the recovery of around 75% by volume of the butane derivatives, and 85 to 90% by volume of the pentane derivatives, and higher-boiling constituents from the gas stream.

The basic absorption process above can be modified to improve its effectiveness, or to target the extraction of specific gas stream liquids. In the refrigerated oil absorption method, where the lean oil is cooled through refrigeration, propane recovery can be upwards of 90% by volume, and approximately 40% by volume of the ethane can be extracted from the gas stream. Extraction of the other, higher-boiling liquids can be close to 100% by volume using this process.

The absorption method, on the other hand, uses an absorbing oil to separate the methane from the gas stream liquids. While the gas stream is passed through an absorption tower, the absorption oil (lean oil) soaks up a large amount of the gas liquids. The absorption oil (enriched oil), now containing gas liquids, exits the base of the tower after which the enriched oil is fed into distillers where the blend is heated to above the boiling point of the gas liquids, while the oil remains fluid. The absorption oil is recycled while the gas liquids are cooled and directed to a fractionator tower. Another absorption method that is often used is the refrigerated oil absorption method where the lean oil is chilled rather than heated, a feature that has the potential to enhance recovery rates.

More specifically, to allow the process to operate at low temperatures, the feed gas must be injected with ethylene glycol solution to avoid hydrate formation in the heat exchangers. The feedstock (the gas stream) is cooled by propane refrigeration and separated in a cold separator, typically at approximately -18°C (0°F). The separator liquid is sent to the ethane recovery unit (the deethanizer) while the separator vapor is routed to the absorber operating at 400 psig. Refrigerated lean oil is used to absorb the higher molecular weight hydrocarbons (the C3+ constituents) from the gas stream thereby producing a lean gas and a propane rich bottom which is sent to the deethanizer. The deethanizer operates at a lower pressure, typically at 200 psig, producing an ethane rich gas and a rich oil bottom containing the C3+ components.

The overhead stream from the deethanizer is compressed to the sales gas pipeline or used as fuel gas. The bottom product is further processed in a rich oil still which regenerates a lean oil to be recycled back to the absorber and an overhead distillate containing the C3+ constituents. The C3+ stream can be fractionated in a propane recovery unit (the depropanizer) which produces the propane and butane product. Because of the high-boiling material of the lean oil, a heater is used in the rich oil still. If necessary, the lean oil composition can be controlled using a lean oil still (not shown) to remove the heavy tails of the lean oil from the process.

See also: Absorption, Gas Cleaning, Gas Processing, Gas Treating.

Absorption Tower

An absorption tower (also known as a scrubbing tower) is a long vertical column that typically contains packed bed which is used for absorbing gases from gas streams. The gas is introduced at the bottom of the column and the absorbing liquid, often water, passes in at the top and falls down against the countercurrent of gas. In the tower, the higher-boiling (gasoline-range) hydrocarbon derivatives are partially absorbed by a liquid in the form of falling droplets.

The gas stream is introduced into the lower portion of the tower and flows upwards while making contact with a washing fluid. The tower is provided with one or several washing stages, each comprising one or several venturi tubes through which the gas is given a speed increase and the washing fluid is discharged through fluid nozzles in the gas flow path. Liquid distribution in the tower occurs in the gas flow in directions forming such angles to the vertical that the fluid flow will not fall backwards and it is preferential that the gas flow is not interrupted.

There are many devices that fall into the category of absorption tower – packed towers (packed columns) are most frequently used to remove contaminants from a gas stream. However, packed towers can also be used to remove volatile components from a liquid stream by contacting it with an inert gas (stripping). They are also used in distillation applications where the separation is particularly difficult due to close boiling components.

The packed tower consists of a vertical hollow column that is filled with small solid pieces (the packing) which occupy the space but leave voids between the pieces. Thus a liquid stream can be introduced into the top of the tower and flow down over the surface of the pieces, creating a large surface area for a given volume of liquid. The gas to be treated is introduced into the tower and flows through the voids where it comes into intimate contact with the surface of the liquid. The packings are divided into three principal types: (i) dumped packings, which is the loose packing method, (ii) stacked packings, which is the dense packing method, and (iii) structured packing, which is the ordered packing method.

The diameter of a packed absorption tower depends on the quantities of gas and liquid handled, their properties, and the ratio of one stream to the other. The height of the tower, and hence the total volume of packing, depends on the magnitude of the desired concentration changes and on the rate of mass transfer per unit of packed volume.

Accuracy and Precision in Analysis

Analysis is the means by which any fuel (fossil or alternative, especially a biomass-derived) fuel is characterized and accuracy and precision are required otherwise the analytical data are suspect and cannot be used with any degree of certainty. This is also especially true of analytical data that is reused for commercial operations where the fuel may be sold on the basis of heat content.

Thus, the *accuracy* of a test is a measure of how close the test result will be to the true value of the property being measured. As such the accuracy can be expressed as the *bias* between the test result and the true value. However, the *absolute accuracy* can only be established if the true value is known. In the simplest sense, a convenient method to determine a relationship between two measured properties is to plot one against the other. Such an exercise will provide either a line fit of the points or a spread that may or may not be within the limits of experimental error. The data can then be used to determine the approximate accuracy of one or more points employed in the plot. For example,

a point that lies outside the limits of experimental error (a *flyer*) will indicate an issue of accuracy with that test and the need for a repeat determination.

However, the graphical approach is not appropriate for finding the absolute accuracy between more than two properties. The well-established statistical technique of regression analysis is more pertinent to determining the accuracy of points derived from one property and any number of other properties. There are many instances in which relationships of this sort enable properties to be predicted from other measured properties with as good precision as they can be measured by a single test. It would be possible to examine in this way the relationships between all the specified properties of a product and to establish certain key properties from which the remainder could be predicted, but this would be a tedious task.

An alternative approach to that of picking out the essential tests in a specification using regression analysis is to take a look at the specification as a whole, and extract the essential features (termed *principal components analysis*).

Principal components analysis involves an examination of set of data as points in n -dimensional space (corresponding to a number (n) of original tests) and determines (first) the direction that accounts for the biggest variability in the data (*first principal component*). The process is repeated until n principal components are evaluated, but not all of these are of practical importance since some may be attributable purely to experimental error. The number of significant principal components shows the number of independent properties being measured by the tests considered.

Following from this, it is necessary to establish the number of independent properties that are necessary to predict product performance in service with the goals of rendering any specification more meaningful and allowing a high degree of predictability of product behavior. On a long-term approach it might be possible to obtain new tests of a fundamental nature to replace, or certainly to supplement, existing tests. In the short term, selecting the best of the existing tests to define product quality is the most beneficial route to predictability.

On the other hand, the *precision* of a test method is the variability between test results obtained on the same material, using a specific test method. The precision of a test is usually unrelated to its accuracy. The results may be precise, but not necessarily accurate. In fact, the precision of an analytical method is the amount of scatter in the results obtained from multiple analyses of a homogeneous sample. To be meaningful, the precision study must be performed using the exact sample and standard preparation procedures that will be used in the final method. Precision is expressed as repeatability and reproducibility.

The *intra-laboratory precision* or the *within-laboratory precision* refers to the precision of a test method when the results are obtained by the same operator in the same laboratory using the same apparatus. In some cases, the precision is applied to data gathered by a different operator in the same laboratory using the same apparatus. Thus, intra-laboratory precision has an expanded meaning insofar as it can be applied to laboratory precision.

Repeatability or repeatability interval of a test (r) is the maximum permissible difference due to test error between two results obtained on the same material in the same laboratory.

$$r = 2.77 \times \text{standard deviation of test}$$

The repeatability interval (r) is, statistically, the 95% probability level or the differences between two test results are unlikely to exceed this repeatability interval more than five times in a hundred.

The *inter-laboratory precision* or the *between-laboratory precision* is defined in terms of the variability between test results obtained on the aliquots of the same homogeneous material in different laboratories using the same test method.

The term *reproducibility* or *reproducibility interval* (R) is analogous to the term repeatability but it is the maximum permissible difference between two results obtained on the same material but now in different laboratories. Therefore, differences between two or more laboratories should not exceed the reproducibility interval more than five times in a hundred.

$$R = 2.77 \times \text{standard deviation of test}$$

Acetogenesis

Acetogenesis is the third phase of anaerobic digestion in which simple molecules created through the acidogenesis phase are further digested by acetogens to produce largely acetic acid, as well as carbon dioxide and hydrogen.

The acid-producing bacteria, involved in the second step, convert the intermediates of fermenting bacteria into acetic acid (CH_3COOH), hydrogen (H_2) and carbon dioxide (CO_2). These bacteria are facultatively anaerobic and can grow under acid conditions. To produce acetic acid, the bacteria need oxygen and carbon. For this, they use the oxygen solved in the solution or bounded-oxygen whereby the acid-producing bacteria create an anaerobic condition which is essential for the methane producing microorganisms. Moreover, these bacteria reduce the compounds with a low molecular weight into alcohols, organic acids, amino acids, carbon dioxide, hydrogen sulfide and traces of methane.

From a chemical standpoint, this process is partially endergonic (i.e., only possible with energy input), since bacteria alone are not capable of sustaining that type of reaction. An endergonic reaction is a chemical reaction in which total amount of energy is a loss – it takes more energy to initiate the reaction than the energy produced by the reaction and, thus, the total energy is a negative net result.

An acetogen is a microorganism that generates acetate (CH_3COO^-) as an end product of anaerobic respiration (fermentation) and can produce, in most cases, acetate as the end product) from two molecules of carbon dioxide (CO_2) and four molecules of molecular hydrogen (H_2). This process (acetogenesis) is different from acetate fermentation, although both occur in the absence of molecular oxygen (O_2) and produce acetate. Acetogens are found in a variety of habitats, generally those that are anaerobic (lack oxygen). Thus, acetogenesis is a process through which acetate is produced from carbon dioxide and an electron source (such as hydrogen and carbon monoxide) by anaerobic bacteria. In this reaction, carbon dioxide is reduced to carbon monoxide and formic acid (HCO_2H) or directly into a formyl group, the formyl group is reduced to a methyl group and then combined with the carbon monoxide and Coenzyme A produce acetyl-CoA. Two specific enzymes participate on the carbon monoxide side of the pathway: (i) CO-dehydrogenase, which catalyzes the reduction of the carbon dioxide and (ii) acetyl CoA synthase, which combines the resulting carbon monoxide with a methyl group to give acetyl-CoA.

The key aspects of the acetogenic pathway are several reactions that include the reduction of carbon dioxide to carbon monoxide and the attachment of the carbon monoxide to a methyl group. The first process is catalyzed by specific enzymes (carbon monoxide dehydrogenase enzymes) and the coupling of the methyl group (provided by methylcobalamin) and the carbon monoxide is catalyzed by acetyl CoA synthetase.

The accumulation of hydrogen can inhibit the metabolism of the acetogenic bacteria and present knowledge suggests that hydrogen may be a limiting feedstock for methanogens. This assumption is based on the fact that addition of hydrogen-producing bacteria to the natural biogas-producing consortium increases the daily biogas production. At the end of the degradation chain, two groups of methanogenic bacteria produce methane from acetate or hydrogen and carbon dioxide. These bacteria are strict anaerobes and require a lower redox potential for growth than most other anaerobic bacteria.

Acid Catalyst

A catalyst alters the rate of a reaction without changing the reaction thermodynamic parameters through another route. Normally, the one in the energy of the transition state is lower. There are two types of catalysts which can affect the reaction pathway: (i) homogeneous catalysis and (ii) heterogeneous catalysts.

Since the acidity of the catalyst support reflects the reaction pathway and plays a key role in the catalyst performance, it is possible to differentiate between homogeneous and heterogeneous catalyst. The homogeneous catalyst has lower ability of acidic sites rather than heterogeneous catalysts and it requires higher temperature in its reaction system, whereas the solid structure and the surface of a heterogeneous catalyst give its ability for higher strength and locations for acidic sites.

Many mineral acid catalysts that are active in homogeneous catalysis can be made suitable for heterogeneous catalysis by supporting the catalyst on an inorganic oxide. Strongly acidic heterogeneous catalysts are prepared by supporting Brønsted acids such as trifluoro-sulfonic acid, sulfuric acid, phosphoric acid, and Lewis acids (such as boron trifluoride, BF_3 , and antimony pentafluoride, SbF_5) on high surface area oxides such as silica, SiO_2 , alumina, Al_2O_3 , and zirconia, ZrO_2). In particular, supported phosphoric acid on silica is still widely used, and $\text{BF}_3\text{-}\gamma\text{-Al}_2\text{O}_3$ and $\text{H}_2\text{SO}_4\text{-ZrO}_2$ possess acidic sites that enable them to perform reactions that other solids are not strong enough acids to catalyze. Supported acids are difficult to characterize and are highly dependent on the methods and materials used in their preparation but do offer a suitable alternative for reactions that require strong and even super acidity.

Acid Deposition

Acid deposition is the scientific term used to describe acid rain (which includes including acid fog, acid sleet, and acid snow).

Acid deposition (acid rain) occurs when sulfur dioxide (SO_2) and, to a lesser extent, NO_x emissions are transformed in the atmosphere and return to the earth as dry deposition or in rain, fog, or snow. Acid rain is another environmental problem that affects many industrialized area of the world resulting in damage crops, forests, wildlife populations, and causing respiratory and other illnesses in humans.

When atmospheric pollutants such as sulfur dioxide and nitrogen oxides mix with water vapors in the air, they are converted to sulfuric and nitric acids.

Sulfur dioxide with water in produce sulfurous acid:

In the gas phase, sulfur dioxide is oxidized by reaction with the hydroxyl radical via an intermolecular reaction:

In the presence of water sulfur trioxide (SO_3) is converted rapidly to sulfuric acid:

Nitric acid is formed by the reaction of water with nitrogen dioxide and by the reaction of carbon dioxide with water:

Although carbonic acid is a weaker acid than nitric acid, sulfurous acid, and sulfuric acid, it does, however, contribute to acid rain which, in high concentrations, can cause damage to natural environments including forests and freshwater lakes.

Acid deposition can be classified as wet deposition such as acid rain, snow, sleet and fog or dry deposition such as deposition as particulate matter even less than $PM_{2.5}$. Effects of acid rain can be either chronic or episodic. Chronic acidification is a long-term effect due to years of acid rain. Episodic acidification is due to heavy rain storms; it also occurs in spring as concentrated nitrate and sulphate in lower layer of snow pack get released when snow melts. A second method of acid deposition is known as dry deposition. Whilst wet deposition involves the precipitation of acids, dry deposition occurs when the acids are first transformed chemically into gases and salts, before falling under the influence of gravity back to Earth. Sulfur dioxide, for example, is deposited as a gas and as a salt.

The gases present in acid deposition are found to occur naturally in the environment. They are given off from a number of sources including volcanic eruptions and the rotting of vegetation. They become a problem when humans produce the gases in large amounts and at high concentrations by the burning of fossil fuels. It is arguable which gives off the most acid gases – fossil fuels or natural events such as eruption of volcanoes. The distances that pollutant gases travel means that acid deposition is an international or trans-boundary problem. This means that acid pollutants are not necessarily deposited in the same country where they were produced.

Acid rain falling over regions with alkaline soils or rocks is quickly neutralized but in areas with little acid-neutralizing capacity is the biosphere sensitive to acid rain. Over North America these areas include New England, eastern Canada, and mountainous regions, which have granitic bedrock and thin soils.

In areas where the biosphere is sensitive to acid rain, there has been ample evidence of the negative effects of acid rain on freshwater ecosystems. Elevated acidity in a lake or river is directly harmful to fish because it corrodes the organic gill material and attacks the calcium carbonate skeleton. In addition, the acidity dissolves toxic metals such as aluminum from the sediments. There is also ample evidence that acid rain is harmful to terrestrial vegetation, mostly because it leaches nutrients such as potassium and allows them to exit the ecosystem by runoff.

See also: Acid Rain.

Acid Gas

Many gas streams, while ostensibly being hydrocarbon in nature, contain large amounts of acid gases such as hydrogen sulfide (H_2S) and carbon dioxide (CO_2) and acid gas is natural as or even process gas that contains significant amounts of hydrogen sulfide, carbon dioxide, or similar contaminants. The terms acid gas and sour gas are often (incorrectly) treated as synonyms.

A gas stream containing hydrogen sulfide or carbon dioxide is referred to as sour and a gas stream that is free from hydrogen sulfide is referred to as *sweet*. The corrosive nature of hydrogen sulfide and carbon dioxide in the presence of water (giving rise to an acidic aqueous solution) and because of the toxicity of hydrogen sulfide and the lack of heating value of carbon dioxide. However, because gas streams from a variety of renewable sources have a wide range of composition, including the concentration of the two acid gases, processes for the removal of acid gases vary and are subject to choice based upon the desired end-product.

In addition to hydrogen sulfide and carbon dioxide, a gas stream may contain other contaminants, such as mercaptan derivatives (such as methyl mercaptan, CH_3SH , and carbonyl sulfide, COS). The presence of these impurities may eliminate some of the sweetening processes since some processes remove large amounts of acid gas but not to a sufficiently low concentration. On the other hand, there are those processes that are not designed to remove (or are incapable of removing) large amounts of acid gases. However, these processes are also capable of removing the acid gas impurities to low levels when the acid gases are there in low to medium concentrations in the gas.

To sweeten (i.e., remove sulfur compounds from) the high acid content gas, it is first pre-scrubbed to remove entrained brine, hydrocarbons, and other constituents. The sour gas then enters an absorber, where lean amine solution chemically absorbs the acid gas components, as well as a small portion of hydrocarbons, rendering the gas ready for processing and sale. An outlet scrubber removes any residual amine, which is regenerated for recycling. Hydrocarbon contaminants entrained in the amine can be separated in a flash tank and used as fuel gas or sold.

Process efficiency can be optimized by mixing different types of amine to increase absorption capacity, by increasing the amine concentration, or by varying the temperature of the lean amine absorption process.

Acid Gas Removal

Acid gas removal (acid gas treating) is the removal of acidic gases such as hydrogen sulfide and carbon dioxide from gas streams. In addition to removal water and gas stream liquids removal, one of the most important parts of gas processing involves the removal of hydrogen sulfide and carbon dioxide. Gas from some sources contains significant amounts of hydrogen sulfide and carbon dioxide and is usually referred to as sour gas. Sour gas is undesirable because the sulfur compounds it contains can be extremely harmful, even lethal, to breathe and the gas can also be extremely corrosive. The process for removing hydrogen sulfide from sour gas is commonly referred to as sweetening the gas.

Acid gas removal (i.e., removal of carbon dioxide and hydrogen sulfide from gas streams) is achieved by application of one or both of the following process types: (i) absorption and (ii) adsorption.

Acid gas removal processes involve the chemical reaction of the acid gases with a solid oxide (such as iron oxide) or selective absorption of the contaminants into a liquid (such as ethanolamine) that is passed countercurrent to the gas. Then the absorbent is stripped of the gas components (regeneration) and recycled to the absorber. The process design will vary and, in practice, may employ multiple absorption columns and multiple regeneration columns.

Liquid absorption processes (which usually employ temperatures below 50°C (120°F) are classified either as physical solvent processes or chemical solvent processes. The former processes employ an organic solvent, and absorption is enhanced by low temperatures, or high pressure, or both. Regeneration of the solvent is often accomplished readily. In chemical solvent processes, absorption of the acid gases is achieved mainly by use of alkaline solutions such as amines or carbonates. Regeneration (desorption) can be achieved by the use of reduced pressure and/or high temperature, whereby the acid gases are stripped from the solvent.

Adsorbers are widely used to increase a low gas concentration prior to incineration unless the gas concentration is high in the inlet air stream. Adsorption also is employed to reduce problem odors from gases. There are several limitations to the use of adsorption systems, but it is generally felt that the major one is the requirement for minimization of particulate matter and/or condensation of liquids (e.g., water vapor) that could mask the adsorption surface and drastically reduce its efficiency.

The precise area of application of a given process is difficult to define, and several factors must be considered: (i) the types and concentrations of contaminants in the gas, (ii) the degree of contaminant removal desired, (iii) the selectivity of acid gas removal required, (iv) the temperature, pressure, volume, and composition of the gas to be processed, (v) the carbon dioxide-hydrogen sulfide ratio in the gas, and (vi) the desirability of sulfur recovery due to process economics or environmental issues.

A number of processes are available for the removal of hydrogen sulfide from gas streams. These processes can be categorized as those based on physical absorption, adsorption by a solid, or chemical reaction. Physical absorption processes suffer from the fact that they frequently encounter difficulty in reaching the low concentrations of hydrogen sulfide required in the sweetened gas stream.

Solid bed adsorption processes suffer from the fact that they are generally restricted to low concentrations of hydrogen sulfide in the entering sour gas stream. The development of a short-cycle adsorption unit for hydrogen sulfide removal might help remove part of this low-concentration restriction for the solid bed absorption processes. In general, chemical processes are able to meet the regulated hydrogen sulfide levels.

The most well-known hydrogen sulfide removal process is based on the reaction of hydrogen sulfide with iron oxide (iron sponge process or dry box method) in which the gas is passed through a bed of wood chips impregnated with iron oxide:

The bed is then regenerated by passage of air through the bed:

The bed is maintained in a moist state by circulation of water or a solution of soda ash.

The method is suitable only for small-to-moderate quantities of hydrogen sulfide. Approximately 90% of the hydrogen sulfide can be removed per bed but bed clogging by elemental sulfur occurs and the bed must be discarded and the use of several beds in series is not usually economical. Removal of larger amounts of hydrogen sulfide from gas streams requires continuous processes, such as the Ferrox process or the Stretford process.

The Ferrox process is based on the same chemistry as the iron oxide process except that it is fluid and continuous. The Stretford process employs a solution containing vanadium salts and anthraquinone disulfonic acid.

Most hydrogen sulfide removal processes involve fairly simple chemistry with the potential for regeneration with return of the hydrogen sulfide. However, if the quantity involved does not justify installation of a sulfur recovery plant, usually a Claus plant, it will be necessary to select a process which produces elemental sulfur directly:

The conversion can be achieved by reacting the hydrogen sulfide gas directly with air in a burner reactor if the gas can be burnt with a stable flame.

Other equilibria which should be taken into account are the formation of sulfur dimer, hexamer, and octamer as well as the dissociation of hydrogen sulfide:

Carbonyl sulfide and carbon disulfide may be formed, especially when the gas is burned with less than the stoichiometric amount of air in the presence of hydrocarbon impurities or large amounts of carbon dioxide.

Equilibrium conversion is almost complete (approximately 99 to 100%) at relatively low temperatures and diminishes at first at higher temperatures, in accordance with the exothermic nature of the reaction. A further rise in temperature causes the equilibrium conversion to increase again. This is a consequence of the dissociation of the polymeric sulfur into monatomic sulfur.

Catalysis by alumina is necessary to obtain good equilibrium conversions: the thermal Claus reaction is fast only above 500°C (930°F). There is also a lower temperature limit which is not caused by low rates but by sulfur condensation in the catalyst pores and consequent deactivation of the catalyst. The lower limit at which satisfactory operation is still possible depends on the pore size and size distribution of the catalyst; with alumina-based catalysts having wide pores, the conversion proceeds satisfactorily at approximately 200°C (390°F).

In all Claus process configurations several conversion steps in adiabatic reactors are used, with intermittent and final condensation of the sulfur produced. There are three main process forms, depending on the concentration of hydrogen sulfide and other sulfur compounds in the gas to be converted, i.e., the straight-through, the split-flow oxidation process.

The straight-through process is applicable when the gas stream contains more than 50% v/v hydrogen sulfide. Feed gases of this type can be burnt with the stoichiometric amount of air to give sulfur. The combustion reactor is followed by a combined waste heat boiler and sulfur condenser from which liquid sulfur and steam are obtained. The gases are then reheated by in-line fuel combustion to the temperature of the first catalytic convertor, which is usually kept at approximately 350°C (660°F) to decompose any carbonyl sulfide and any carbon disulfide formed in the combustion step. A second catalytic convertor, operating at as low a temperature as possible, is also employed to obtain high final conversions.

Molecular sieves and membranes have been undergoing development for the removal of hydrogen sulfide and carbon dioxide from gas streams, especially when the amount of the acid gas(es) is low. The most appropriate use of the sieves and the membranes would be use of the sieve to selectively remove hydrogen sulfide and/or use of membranes permeable to hydrogen sulfide but not to carbon dioxide.

See also: Gas Cleaning, Gas Processing, Gas Treating.

Acid Gas Removal Processes

The primary process for sweetening sour gas streams is similar to the processes of glycol dehydration and removal of gas stream liquids by absorption. In this case, however, amine (olamine) solutions are used to remove the hydrogen sulfide (the amine process). The sour gas is run through a tower, which contains the olamine solution.

There are two principle amine solutions used, monoethanolamine (MEA) and diethanolamine (DEA). Either of these compounds, in liquid form, will absorb sulfur compounds from the gas stream as it passes through. The effluent gas is virtually free of sulfur compounds, and thus loses its sour gas status; the amine solution used can be regenerated for reuse.

Although most sour gas sweetening involves the amine absorption process, it is also possible to use solid desiccants like iron sponge to remove hydrogen sulfide and carbon dioxide. Treatment of gas to remove the acid gas constituents (hydrogen sulfide and carbon dioxide) is most often accomplished by contact of the gas stream with an alkaline solution. The most commonly used treating solutions are aqueous solutions of the ethanolamine or alkali carbonates.

A considerable number of other treating agents have been developed in recent years. Most of these newer treating agents rely upon physical absorption and chemical reaction. When only carbon dioxide is to be removed in large quantities or when only partial removal is necessary, a hot carbonate solution or one of the physical solvents is the most economical selection.

The most well-known hydrogen sulfide removal process is based on the reaction of hydrogen sulfide with iron oxide (often also called the iron sponge process or the dry box method) in which the gas is passed through a bed of wood chips impregnated with iron oxide.

The iron oxide process is the oldest and still the most widely used batch process for sweetening gas streams and separation the gas liquids. The process was implemented during the 19th century. In the process, the sour gas is passed down through the bed. In the case where continuous regeneration is to be utilized a small concentration of air is added to the sour gas before it is processed. This air serves to continuously regenerate the iron oxide, which has reacted with hydrogen sulfide, which serves to extend the on-stream life of a given tower but probably serves to decrease the total amount of sulfur that a given weight of bed will remove.

The process is usually best applied to gases containing low to medium concentrations (300 ppm) of hydrogen sulfide or mercaptans. This process tends to be highly selective and does not normally remove significant quantities of carbon dioxide. As a result, the hydrogen sulfide stream from the process is high purity. The use of iron sponge process for sweetening sour gas is based on adsorption of the acid gases on the surface of the solid sweetening agent followed by chemical reaction of ferric oxide (Fe_2O_3) with hydrogen sulfide:

The reaction requires the presence of slightly alkaline water and a temperature below 43°C (110°F) and bed alkalinity ($\text{pH} = 8$ to 10) should be checked regularly, usually on a daily basis. The pH level is be maintained through the injection of caustic soda with the water. If the gas does not contain sufficient water vapor, water may need to be injected into the inlet gas stream.

The ferric sulfide produced by the reaction of hydrogen sulfide with ferric oxide can be oxidized with air to produce sulfur and regenerate the ferric oxide:

The regeneration step is exothermic and air must be introduced slowly so the heat of reaction can be dissipated. If air is introduced quickly the heat of reaction may ignite the bed. Some of the elemental sulfur produced in the regeneration step remains in the bed. After several cycles, this sulfur will form a cake over the ferric oxide, decreasing the reactivity of the bed. Typically, after 10 cycles the bed must be removed and a new bed introduced into the vessel.

The iron oxide process is one of several metal oxide-based processes that scavenge hydrogen sulfide and organic sulfur compounds (mercaptans) from gas streams through reactions with the solid based chemical adsorbent. They are typically non-regenerable, although some are partially regenerable, losing activity upon each regeneration cycle. Most of the processes are governed by the reaction of a metal oxide with hydrogen sulfide to form the metal sulfide. For regeneration, the metal oxide is reacted with oxygen to produce elemental sulfur and the regenerated metal oxide. In addition, to iron oxide, the primary metal oxide used for dry sorption processes is zinc oxide.

In the zinc oxide process, the zinc oxide media particles are extruded cylinders 3-4 mm in diameter and 4-8 mm in length and react readily with the hydrogen sulfide:

At increased temperatures (205 to 370°C, 400 to 700°F), zinc oxide has a rapid reaction rate, therefore providing a short mass transfer zone, resulting in a short length of unused bed and improved efficiency.

Removal of larger amounts of hydrogen sulfide from gas streams requires a continuous process, such as the Ferrox process or the Stretford process.

The Ferrox process is based on the same chemistry as the iron oxide process except that it is fluid and continuous. The Stretford process employs a solution containing vanadium salts and anthraquinone disulfonic acid. Most hydrogen sulfide removal processes return the hydrogen sulfide unchanged, but if the quantity involved does not justify installation of a sulfur recovery plant (usually a Claus plant), it is necessary to select a process that directly produces elemental sulfur.

The processes using ethanolamine and potassium phosphate are now widely used. The ethanolamine process, known as the Girbotol process, removes acid gases (hydrogen sulfide and carbon dioxide) from liquid hydrocarbons as well as from natural and from refinery gases. The Girbotol process uses an aqueous solution of ethanolamine ($\text{H}_2\text{NCH}_2\text{CH}_2\text{OH}$) that reacts with hydrogen sulfide at low temperatures and releases hydrogen sulfide at high temperatures. The ethanolamine solution fills a tower called an absorber through which the sour gas is bubbled. Purified gas leaves the top of the tower, and the ethanolamine solution leaves the bottom of the tower with the absorbed acid gases. The ethanolamine solution enters a reactivator tower where heat drives the acid gases from the solution. Ethanolamine solution, restored to its original condition, leaves the bottom of the reactivator tower to go to the top of the absorber tower, and acid gases are released from the top of the reactivator.

The process using potassium phosphate is known as phosphate desulfurization, and it is used in the same way as the Girbotol process to remove acid gases from liquid hydrocarbons as well as from gas streams. The treatment solution is a water solution of potassium phosphate (K_3PO_4), which is circulated through an absorber tower and a reactivator tower in much the same way as the ethanolamine is circulated in the Girbotol process; the solution is regenerated thermally.

Moisture may be removed from hydrocarbon gases at the same time as hydrogen sulfide is removed. Moisture removal is necessary to prevent harm to anhydrous catalysts and to prevent the formation of hydrocarbon hydrates (such as $\text{C}_3\text{H}_8 \cdot 18\text{H}_2\text{O}$) at low temperatures. A widely used dehydration and desulfurization process is the glycol-amine process, in which the treatment solution is a mixture of ethanolamine and a large amount of glycol. The mixture is circulated through an absorber and a reactivator in the same way as ethanolamine is circulated in the Girbotol process. The glycol absorbs moisture from the hydrocarbon gas passing up the absorber; the ethanolamine absorbs hydrogen sulfide and carbon dioxide. The treated gas leaves the top of the absorber; the spent ethanolamine-glycol mixture enters the reactivator tower, where heat drives off the absorbed acid gases and water.

Other processes include the Alkazid process for removal of hydrogen sulfide and carbon dioxide using concentrated aqueous solutions of amino acids. The hot potassium carbonate process decreases the acid content of natural and refinery gas from as much as 50% to as low as 0.5% and operates in a unit similar to that used for amine treating.

The Giammarco-Vetrocoke process is used for hydrogen sulfide and/or carbon dioxide removal. In the hydrogen sulfide removal section, the reagent consists of sodium or potassium carbonates containing a mixture of arsenite derivatives (such as sodium arsenite, NaAsO_2) and arsenate derivatives (such as sodium arsenate, Na_3AsO_4); the carbon dioxide removal section utilizes hot aqueous alkali carbonate solution activated by arsenic trioxide or selenous acid or tellurous acid.

Molecular sieves are highly selective for the removal of hydrogen sulfide (as well as other sulfur compounds) from gas streams and over continuously high absorption efficiency. They are also an effective means of water removal and thus offer a process for the simultaneous dehydration and desulfurization of gas. Gas that has excessively high water content may require upstream dehydration, however.

The molecular sieve process is similar to the iron oxide process. Regeneration of the bed is achieved by passing heated clean gas over the bed. As the temperature of the bed increases, it releases the adsorbed hydrogen sulfide into the regeneration gas stream. The sour effluent regeneration gas is sent to a flare stack, and up to 2% of the gas seated can be lost in the regeneration process. A portion of the gas stream may also be lost by the adsorption of hydrocarbon components by the sieve.

Acid Gas Scrubbing – Basic Solid or Solution

Sulfur dioxide is an acid gas and thus the typical sorbent slurries or other materials used to remove the sulfur dioxide from the flue gases are alkaline. The reaction taking place in wet scrubbing using a limestone (CaCO_3) slurry produces calcium sulfite (CaSO_3):

When wet scrubbing with a lime [Ca(OH)_2] slurry, the reaction also produces calcium sulfite:

When wet scrubbing with a magnesium hydroxide [Mg(OH)_2] slurry, the reaction produces magnesium sulfite (MgSO_3):

In some designs, the calcium sulfite is oxidized to produce calcium sulfate (gypsum, $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$):

Seawater is also used to absorb sulfur dioxide; the SO_2 is absorbed in the water and when oxygen is added reacts to form sulfate ions (SO_4^{2-}) and free protons (H^+) which result in the release of carbon dioxide from the carbonates in the seawater:

See also: Gas Cleaning, Gas Processing, Gas Treating.

Acid Gas Scrubbing – Wet Scrubbers

To promote maximum gas-liquid surface area and residence time, a number of wet scrubber designs have been used in wet flue gas desulfurization systems, including spray towers, venturi scrubbers, plate towers, and mobile packed beds.

Scale buildup, plugging, or erosion affect the dependability and absorber efficiency of flue gas desulfurization systems and the trend has been to use simple scrubbers such as spray towers instead of more complicated ones. The configuration of the tower may be vertical or horizontal, and flue gas can flow co-currently, counter-currently, or cross-currently with respect to the liquid. The chief drawback of spray towers is that they require a higher liquid-to-gas ratio requirement for equivalent sulfur dioxide removal than other absorber designs.

A wet scrubber is a form of pollution control technology and is a device that removes pollutants from gas streams. In a wet scrubber, the polluted gas stream is brought into contact with the scrubbing liquid, by spraying it with the liquid, by forcing it through a pool of liquid, or by some other contact method, so as to remove the pollutants.

Scrubbers can be designed to collect particulate matter and/or gaseous pollutants. Wet scrubbers remove dust particles by capturing them in liquid droplets. Wet scrubbers remove pollutant gases by dissolving or absorbing them into the liquid. Any droplets that are in the scrubber inlet gas must be separated from the outlet gas stream by means of another device referred to as a mist eliminator. Also, the resultant scrubbing liquid must be treated prior to any ultimate discharge or being reused in the plant.

There are numerous configurations of scrubbers and scrubbing systems, all designed to provide good contact between the liquid and polluted gas stream. Examples include a venturi scrubber and the mist eliminator for a venturi scrubber is often a cyclone separator whereas the packed tower design has the mist eliminator built into the top of the tower.

The ability of a wet scrubber to collect small particles is often directly proportional to the power input into the scrubber. Low-energy devices such as spray towers are used to collect particles larger than 5 micrometers. To obtain high efficiency removal of 1 micrometer (or less) particles generally requires high-energy devices such as venturi scrubbers or augmented devices such as condensation scrubbers. Additionally, a meticulously designed and operated entrainment separator or mist eliminator is important to achieve high removal efficiencies. The greater the number of liquid droplets that are not captured by the mist eliminator the higher the potential emission levels.

Wet scrubbers that remove gaseous pollutants are referred to as absorbers. Good gas-to-liquid contact is essential to obtain high removal efficiencies in absorbers. A number of wet scrubber designs are used to remove gaseous pollutants, with the packed tower and the plate tower being the most common.

If the gas stream contains both particle matter and gases, wet scrubbers are generally the only single air pollution control device that can remove both pollutants. Wet scrubbers can achieve high removal efficiencies for either particles or gases and, in some instances, can achieve a high removal efficiency for both pollutants in the same system. However, in many cases, the best operating conditions for particles collection are the poorest for gas removal.

In general, obtaining high simultaneous gas and particulate removal efficiencies requires that one of them be easily collected (i.e., that the gases are very soluble in the liquid or that the particles are large and readily captured) or by the use of a scrubbing reagent such as lime (CaO) or sodium hydroxide (NaOH).

For particulate control, wet scrubbers (also referred to as wet collectors) are evaluated against fabric filters and electrostatic precipitators (ESPs).

Wet scrubbers have the ability to handle high temperatures and moisture and in wet scrubbers, the inlet gases are cooled, resulting in smaller overall size of equipment. Also, wet scrubbers can remove both gases and particulate matter and can neutralize corrosive gases. On the other hand, wet scrubbers are subject to corrosion and there is the need for entrainment separation or mist removal to obtain high efficiencies and the need for treatment or reuse of spent liquid.

Acid Hydrolysis

Hydrolysis is any chemical reaction in which a molecule of water ruptures one or more chemical bonds. The term is used broadly for substitution, elimination, and fragmentation reactions in which water is the nucleophile:

Acid hydrolysis is the means by which cellulosic material can be converted to lower molecular weight products and thence to fuels. Although the chemical transformation steps can be complex, using polysaccharide derivatives (such as starch) The overall process can be represented by a series of simplified steps (Table A-3):

Table A-3 Simplified steps that represent the conversion of polysaccharide derivatives to methane.

Polysaccharides			
(<i>Hydrolytic bacteria*</i>)			
	Fatty acids		
	(<i>Acidogenic bacteria*</i>)		
		Organic acids	
		(<i>Acetogenic bacteria</i>)	
			Methanogenic substances**
			(<i>Methanogens</i>)

*The names that are italicized and in parentheses are the active agents that cause the chemical transformation.

**The methanogenic substances are precursors to methane and carbon dioxide.

Large amounts of inexpensive and renewable lignocellulose waste are generated each year from forestry and agricultural production. These include fruit processing residues, dairy industry wastes, corn and sugar by-products, and paper industry wastes. Lignocellulosic biomass can be converted to biofuels such as ethanol and hydrogen via simple sugars. Lignocellulose is a composite of cellulose fibres embedded in a cross-linked lignin-hemicellulose matrix. It gives structure and strength to plants. Although abundant, lignocellulosic waste is difficult to convert to fermentable sugars because of its complex chemical structure: its three major components (cellulose (crystalline and amorphous) hemicellulose and lignin) must be processed separately (Lee et al., 2007).

Cellulose consists of linear, highly ordered chains of glucose and is one of the most abundant biopolymers on the planet. When produced by plants, it has both highly amorphous regions containing large voids and other irregularities as well as tightly packed crystalline regions. It also accumulates in the environment because it is resistant to most forms of degradation. Hemicellulose is a complex polymer of a variety of sugars. This mix of sugars mainly consists of six-carbon and five-carbon sugars. Lignin is a poly-phenolic polymer that fills the spaces in the cell wall between cellulose, hemicellulose, and pectin components. It is covalently linked to hemicellulose and crosslinks different plant polysaccharides, conferring mechanical strength to the cell wall, and by extension, the plant as a whole. The content of cellulose, hemicellulose and lignin in common agricultural residues depends upon the source and origin of the feedstocks. However, because lignocellulosic biomass is so complex, it is difficult to use as a feedstock for bio-fuel. A variety of physical, chemical, and enzymatic processes have been developed to fractionate lignocellulose into the major plant components of hemicellulose, cellulose, and lignin.

Ethanol is produced from lignocellulose via pre-treatment, hydrolysis, fermentation, and distillation. The goal of pre-treatment is to increase the surface area of lignocellulosic material, making the polysaccharides more susceptible to hydrolysis, by separating the xylose and lignin from the crystalline cellulose. Pre-treatment must also avoid the

degradation or loss of precious carbohydrates and avoid the formation of by-products that can inhibit subsequent steps. However, pre-treatment often produces biological inhibitors, which affect fermentation. A large variety of pre-treatment processes have been developed. Common pre-treatments are steam-explosion, acid treatment, biological methods, and comminution. These methods can be used singly or in combination.

Steam explosion involves saturation of the pores of plant materials with steam followed by rapid decompression. The explosive expansion of steam reduces the plant material to separated fibres, increasing accessibility of polysaccharides to subsequent hydrolysis. Ammonia fibre explosion (AFEX) is similar to steam explosion except that liquid ammonia is used. It is effective on agricultural residues but has not been successful in pre-treating woody biomass. *Biological pre-treatments* employ microorganisms that produce lignin-degrading enzymes (ligninase). *Comminution* is an integral part of pre-treatment and uses a hammer mill to produce particle sizes that can pass through 3 mm screen openings.

The mechanisms by which pre-treatments improve the digestibility of lignocellulose are not well understood. Pre-treatment effectiveness has been correlated with removal of hemicellulose and lignin (lignin solubilisation is beneficial for subsequent hydrolysis but may also produce derivatives that inhibit enzyme activity). Some pre-treatments reduce the crystallinity of cellulose, which improves reactivity, but this does not appear to be the key for many successfully pre-treatments.

Hemicellulose is readily hydrolysed to pentoses (5 carbon sugars) but pentoses are difficult to ferment. The cellulose hydrolyses to hexoses (6 carbon sugars). Crystalline cellulose is difficult to hydrolyse but the resulting hexose derivatives are readily fermented. The three basic methods for hydrolysing structural polysaccharides to fermentable sugars (glucose, xylose, arabinose) are concentrated acid hydrolysis, dilute acid hydrolysis and enzymatic hydrolysis.

Acid treatment is the use of acid to hydrolyze cellulosic materials. Two acid processes hydrolyze both hemicellulose and cellulose with minimal pre-treatment beyond comminution of the lignocellulosic material to particles of approximately 1 mm in size. These are concentrated and dilute acid hydrolysis. *Concentrated acid hydrolysis* dissolves carbohydrates in woody biomass to form a homogeneous gelatine with acid where cellulose is extremely susceptible to hydrolysis. Typically, this is achieved with 70 to 90% v/v sulfuric acid (H_2SO_4) at room temperature, leaving lignin. Before fermentation, the solution of oligosaccharides is diluted to 4% v/v sulfuric acid and (i) heated (at the boiling point) for four hours or (ii) processed using an autoclave at 120°C (248°F) for one hour to yield monosaccharides. Following neutralisation with limestone, the sugar solution is fermented. The procedure takes 10 to 12 hours. Concentrated acid hydrolysis is attractive because it is relatively simple, and high sugar yields (approach 100% of theoretical hexose yields in pure samples and 90% in mixed samples which replicate municipal waste mixtures) are achieved. However, corrosion resistant equipment is necessary and acid recovery is expensive.

Dilute acid hydrolysis (1% acid w/w) greatly reduces the amount of acid required to hydrolyse lignocellulose. The process is accelerated at elevated temperatures: 100 to 160°C (212 to 320°F) for hemicellulose and 180 to 220°C (356 to 428°F) for cellulose. The high temperatures cause oligosaccharides released from the lignocellulose to decompose, greatly reducing yields of simple sugars to only 55 to 60% w/w of the theoretical yield. The decomposition products include toxins (acetic acid, furfural) which inhibit fermentation.

Acidity and Alkalinity

Acidity as applied to natural water and wastewater is the capacity of the water to neutralize hydroxyl ions (OH^-). It is analogous to alkalinity, the capacity to neutralize the hydrogen ion (H^+). Acidity is the quantitative expression of the capacity of the water to neutralize a strong base to a designated pH and an indicator of how corrosive water is.

Acidity can be caused by weak organic acids, such as acetic and tannic acids, and strong mineral acids including sulfuric and hydrochloric acids. However, the most common source of acidity in unpolluted water is carbon dioxide in the form of carbonic acid (H_2CO_3). On the other hand, The alkalinity of water refers to the capability of water to neutralize acid in which the water has a buffering capacity – a buffer is a solution to which an acid can be added without changing the concentration of available hydrogen (H^+) ions (without changing the pH) appreciably.

A surface water body, such as a lake, the alkalinity in the water comes mostly from the rocks and land surrounding the lake. Precipitation falls in the watershed surrounding the lake and most of the water entering the lake comes from runoff over the landscape. If the landscape is in an area containing rocks such as limestone then the runoff picks up

chemicals such as calcium carbonate (CaCO_3), which raises the pH and alkalinity of the water. In areas where the geology contains large amounts of granite, for instance, lakes or ponds may have a lower alkalinity.

The acidity and/or the alkalinity of a surface water system can be influenced by the production of the products of the use of non-renewable fuels, such as those carbonaceous fuels that produce carbon dioxide during use or conversion to other forms of energy. However, switching from non-renewable (fossil fuels) to renewable fuels such as biomass is not always the answer. When biomass is directly used as a fuel or when biomass is used as a process feedstock the products can be sufficiently acidic, and it causes a change in the acidity or alkalinity of surface water systems.

See also: Acid Number.

Acid Number

The acid number (also known as the acidity, the acid value, and the neutralization number) is the mass of potassium hydroxide (KOH) in milligrams that is required to neutralize one gram of the substance. The acid number (AN) or the total acid number (TAN) of crude oil is a measure of the amount of carboxylic acid groups and other acidic species (such as phenols and naphthol derivatives) in crude oil and indicates the potential corrosion during refining.

The acid number is used to quantify the amount of acid present, for example in a sample of biodiesel. It is the quantity of base, expressed in milligrams of potassium hydroxide, that is required to neutralize the acidic constituents in 1 g of sample.

$$AN = (V_{eq} - b_{eq})N \frac{56.1}{W_{oil}}$$

In this equation, V_{eq} is the amount of titrant (ml) consumed by the crude oil sample and 1 ml spiking solution at the equivalent point, b_{eq} is the amount of titrant (ml) consumed by 1 ml spiking solution at the equivalent point, and 56.1 is the molecular weight of potassium hydroxide.

The molarity concentration of titrant (N) is calculated as such:

$$N = \frac{1000W_{KHP}}{204.23V_{eq}}$$

In the equation, W_{KHP} is the amount (g) of KHP in 50 ml of KHP standard solution, V_{eq} is the amount of titrant (ml) consumed by 50 ml KHP standard solution at the equivalent point, and 204.23 is the molecular weight of KHP.

There are standard methods for determining the acid number, such as ASTM D974 and (for mineral oils, biodiesel), or specifically for biodiesel (ASTM D664). The acid number (mg KOH/g oil) for biodiesel should be lower than 0.50 mg KOH/g standard fuels.

See also: Acidity and Alkalinity, Neutralization Number.

Acidogenesis

Acidogenesis (sometimes referred to as fermentation) is the biological process that results in further breakdown of the remaining components by acidogenic (fermentative) bacteria. In this process, volatile fatty acids are produced, along with (depending upon the feedstock) ammonia, carbon dioxide, and hydrogen sulfide, as well as other byproducts. Thus:

Whereas the production of volatile fatty acids (VFAs) is increased when the process pH is in excess of 5, the production of ethanol (C_2H_5OH) is characterized by a pH lower than 5 with reaction process coming to a halt at a pH less than 4.

In a balanced bacterial process approximately 50% of the monomers (glucose, xylose, amino acids) and long-chain fatty acids (LCFA) are broken down to acetic acid (CH_3COOH). Twenty percent is converted to carbon dioxide (CO_2) and hydrogen (H_2), while the remaining 30% is broken down into short-chain volatile fatty acids (VFAs). Fatty acids are monocarboxylic acids that are found in fats and have fewer than six carbon atoms whereas long-chain fatty acids. If there is an imbalance in the digester process, the relative level of volatile fatty acids will increase with the risk of accumulation, since the bacteria that degrade the volatile fatty acids have a slow growth rate and cause an imbalance between the various phases of the process. A steady degradation of the volatile chain fatty acids is therefore crucial and often a limiting factor for the biogas process.

Hydrolysis of simple fats results in 1 mol glycerol and 3 mol long-chain fatty acids and, therefore, high proportions of fat in the digester feedstock will result in large amounts of long-chain fatty acids, while large amounts of protein, which contain nitrogen in amino groups ($-NH_2$), will produce large amounts of ammonium/ammonia (NH_4^+/NH_3). In both cases this can lead to inhibition of the subsequent decomposition phase, particularly if the composition of the biomass feedstock varies.

See also: Acetogenesis, Acidogenesis, Acidogenic Digestate, Anaerobic Digestion, Methanogenesis.

Acidogenic Digestate

Anaerobic digestion produces two main products: (i) digestate and (ii) biogas.

The digestate is the material remaining after the anaerobic digestion of a biodegradable feedstock which is then used as a source of renewable energy through the participation of a variety of chemical reactions (Table A-4).

Acidogenic digestate is fibrous and comprises structural plant material which includes lignin and cellulose. It is the acidogenic digestate that possesses the high moisture retention properties and the raw digestate usually also contains minerals and the remains of the micro-organisms (mainly bacteria) which were active during the digestion process. On the other hand, methanogenic digestate is a liquid or sludge (sometimes referred to as a liquor) which is often high in nutrients such as ammonium derivatives and phosphate derivatives.

Table A-4 Common reactions in anaerobic digestion process.

Substrate	Reactions
Alcohol derivatives	$4CH_3OH \rightarrow 3CH_4 + CO_2 + 2H_2O$ $CH_3OH + H_2 \rightarrow CH_4 + H_2O$ $4HCOO^- + 2H^+ \rightarrow CH_4 + 2H_2O$
Monosaccharide derivatives	$C_6H_{12}O_6 + 2H_2O \rightarrow 2H_2 + \text{butyrate} + 2HCO_3^- + 3H^+$ $C_6H_{12}O_6 + 4H_2O \rightarrow 4H_2 + 2CH_3CO_2^- + 2HCO_3^- + 4H^+$
Organic acid derivatives	$C_3H_9CO_2^- + 3H_2O \rightarrow 3H_2 + CH_3CO_2^- + HCO_3^- + H^+$ $C_4H_9CO_2^- + 2H_2O \rightarrow 2H_2 + 2CH_3CO_2^- + H^+$ $HCOO^- + 3H_2 + H^+ \rightarrow CH_4 + 2H_2O$ $CH_3COO^- + H_2O \rightarrow CH_4 + HCO_3^-$ $4CH_3NH_2 + 2H_2O + 4H^+ \rightarrow 3CH_4 + CO_2 + 4NH_4^+$
Methanogenic substances	$4H_2 + HCO_3^- + H^+ \rightarrow CH_4 + 3H_2O$ $4H_2 + 2HCO_3^- + H^+ \rightarrow \text{acetate} + 4H_2O$
Sulfate derivatives	$4H_2 + SO_4^{2-} \rightarrow HS^- + 3H_2O + OH^-$

Key: acetate $CH_3CO_2^-$, propionate $C_3H_9CO_2^-$, butyrate $C_4H_9CO_2^-$

There are four stages to the digestion process, each of which has different characteristics: (i) hydrolysis, which is a chemical reaction where particulate matter (solid matter, such as carbohydrate derivatives) is solubilized and high molecular weight chemicals are converted into lower molecular weight products, (ii) acidogenesis, which is a biological reaction in which lower molecular weight products are converted into volatile fatty acid derivatives, (iii) acetogenesis, which is a biological reaction in which the volatile fatty acid derivatives are converted into acetic acid where volatile fatty acids are converted into acetic acid, carbon dioxide, and hydrogen, and (iv) methanogenesis, which is a biological reaction in which acetate derivatives are converted into methane and carbon dioxide, while hydrogen is consumed. Thus, using carbohydrate derivatives as the example of the digester feedstock:

(i) Hydrolysis

(ii) Acidogenesis

(iii) Acetogenesis

(iv) Methanogenesis

The acidogenic digestate is a stable organic material comprised largely of lignin and chitin, but also of a variety of mineral components in a matrix of dead bacterial cells and some plastic may be present. This resembles domestic compost and can be used as compost or to make low-grade building products such as fiberboard. Another byproduct is a liquid (methanogenic digestate) that is rich in nutrients and can be an excellent fertilizer dependent on the properties of the digester feedstock (Table A-4).

If the feedstock sent to the digester includes low levels of toxic heavy metals (i.e., metals with relatively high density, atomic weight, or atomic number) or synthetic organic chemicals such as pesticides or polychlorobiphenyls, the effect of digestion is to concentrate such materials in the product (i.e., the digester liquor). In such cases further treatment will be required in order to dispose of this liquid properly. In extreme cases, the disposal costs and the environmental risks posed by such materials can offset any environmental gains provided by the use of biogas. This is a significant risk when treating sewage from industrialized catchments.

See also: Anaerobic Digestion, Digester, Digestion.

Acid Rain

Acid rain, or acid deposition, is a broad term that includes any form of precipitation with acidic components, such as sulfuric acid or nitric acid that fall to the ground from the atmosphere in wet or dry forms. This can include rain, snow, fog, hail or even dust that is acidic. Acid rain is another environmental problem that affects much of the eastern United States, damaging crops, forests, wildlife populations, and causing respiratory and other illnesses in humans.

Acid rain is formed when oxides of sulfur and oxides of and nitrogen react with water vapor and other chemicals in the presence of sunlight to form various acidic compounds in the atmosphere. Acid rain results when sulfur dioxide (SO_2) and nitrogen oxides (NO_x) are emitted into the atmosphere and transported by wind and air currents. The sulfur dioxide and nitrogen oxides react with water, oxygen and other chemicals to form sulfuric and nitric acids. These then mix with water and other materials before falling to the ground:

Sulfurous acid

Sulfuric acid

Nitrous acid

Nitric acid

Carbonic acid

These acids can form particulate matter by reaction with, for example, ammonia in the air or with metals particulates.

While a portion of the sulfur dioxide and oxides of nitrogen that cause acid rain is from natural sources such as volcanoes, another part is due to the combustion of carbonaceous fuels. Wind currents can carry these oxides over long distances and across borders making acid rain a global problem and not just for those who live close to these sources.

Other pollutants that are emitted as a result of the combustion process are hydrocarbon derivatives (including unburned fuel and hydrocarbon products of the process) and nitric oxide (NO). When these pollutants build up to sufficiently high levels, a chain reaction occurs from their interaction with sunlight in which the nitric oxide is converted to nitrogen dioxide (NO_2) – a brown gas and at sufficiently high levels can contribute to urban haze. However, nitrogen dioxide can absorb sunlight and break apart to produce oxygen atoms that combine with the oxygen in the air to produce ozone (O_3), a powerful oxidizing agent, and a toxic gas.

A final comment related to acid rain since the formation of the rain is usually also attributed to the combustion of fossil fuels and fossil fuel products. Caution is advised when making such a grandiose statement. Any renewable energy source that contains nitrogen and/or sulfur will contribute to the formation of acid rain. In fact, when air is used as the oxidant in a combustor, part of the nitrogen in the air can be converted to nitrogen oxides and thence to acid rain. In all cases, as the fossil fuel users have learned, the gas from combustors such be cleaned and pollutants – such as the oxides of nitrogen and the oxides of sulfur as well as the oxides of carbon – should be removed as soon as possible after they appear from the combustor.

In areas where the biosphere is sensitive to acid rain, there has been ample evidence of the negative effects of acid rain on freshwater ecosystems. Elevated acidity in a lake or river is directly harmful to fish because it corrodes the organic gill material and attacks the calcium carbonate skeleton. In addition, the acidity dissolves metals that (such as aluminum from the sediments) that are toxic to flora and fauna (including humans). There is also evidence that acid rain is harmful to vegetation by a reverse effect insofar as the rain leaches nutrients (such as potassium) from the soil and allows the nutrients to exit the ecosystem by runoff.

Methods of mitigating acid rain formation include (i) reducing the sulfur content of fuels, (ii) using scrubbers such as flue gas desulfurization, (iii) lime injection multi-stage burning, (iv) fluidized bed combustion, or (iv) circulation dry scrubbing of the gas stream. To reduce the formation of nitrogen oxides, methods such as (i) changing air to fuel ratio, (ii) reducing the combustion temperature, which reduces the formation of the oxides of nitrogen that are formed when air is the combustion oxidant, and (iii) a selective catalytic reduction process in which injection of reactive chemicals such as ammonia (NH_3) to react with the nitrogen oxides and convert them into nitrogen and oxygen, represented simply as:

See also: Biogas, Biomass, Waste, Wood.

Acid Rain – Formation

Acid rain is formed when sulfur dioxide (SO_2) and the nitrogen oxides (NO_x) react with water vapor and oxidants in the presence of sunlight to produce various acidic compounds, such as sulfuric acid and nitric acid.

Acid rain has a pH less than 5.0 and predominantly consists of sulfuric acid (H_2SO_4) and nitric acid (HNO_3). As a point of reference, in the absence of anthropogenic pollution sources the average pH of rain is approximately 6.0 (slightly acidic; neutral pH = 7.0). In summary, the sulfur dioxide that is produced during a variety of processes will react with oxygen and water in the atmosphere to yield environmentally detrimental sulfuric acid. Similarly, nitrogen oxides will also react to produce nitric acid.

Precipitation in the form of rain, snow, ice, and fog causes approximately 50% of these atmospheric acids to fall to the ground as *acid rain*, while approximately 50% fall as dry particles (particulate matter, such as soot or aerosol particles) and gases. Winds can blow the particles and compounds hundreds of miles from their source before they are deposited, and they and their sulfate and nitrate derivatives contribute to atmospheric haze prior to eventual deposition as acid rain. The dry particles that land on surfaces are also washed off by rain, increasing the acidity of runoff.

The principle source of acid rain causing pollutants, sulfur dioxide and nitrogen oxides, are coal-fired power plants. Since natural gas emits virtually no sulfur dioxide, and up to 80% less nitrogen oxides than the combustion of coal, increased use of natural gas could provide for fewer acid rain-causing emissions.

Acid Rain – Mitigation

Acid rain reduction can be done either fuel switching or scrubbing. Fuel switching includes limiting the use of Sulphur-containing fuels such as coal or switching to low sulphur-containing coal or oil, switching to alternative energy sources such as using gas boilers instead of coal or oil boilers, nuclear power generation, using renewable energy sources such as wind, air, wave and geothermal energy.

Gas cleaning (gas scrubbing) includes use of electrostatic precipitators where positively charged sulphur particles are attracted by negatively charged plate or chemical means either wet scrubbing such as injecting water or chemical solution such as flue gas desulphurization (FGS) which has the sulfur dioxide removal rate between 80-95% or dry scrubbers such as lime injection multi stage burning (LIMB) or fluidized bed combustion (FBC or circulation dry scrubber) that react with sulphur in the absence of water medium.

To reduce nitrogen oxides (NO_x), methods such as selective catalytic reduction process (SCR) which has the NO_x reduction rate up to 80% where injection of reactive chemicals such as ammonia reacts with NO_x and convert into nitrogen and oxygen, changing air to fuel ratio and changing the combustion temperature. In automobile NO_x reduction, catalytic converters are used, e.g., three-way catalytic converters: (i) conversion of nitrogen oxides into nitrogen and oxygen, (ii) conversion of carbon monoxide into carbon dioxide, and (iii) conversion of hydrocarbon derivatives into carbon dioxide and water.

See also: Acid Rain, Gas Cleaning, Gas Processing, Gas Treating.

Acid Treating

Acid treating is one of the older treating processes in refining of liquids from renewable sources. This process found importance in the earlier days of crude oil refining and was preferentially used by oil industry for treating middle distillates like gasoline, kerosene, etc., and also for the refining of lubricating oils. Used oil refining was also carried out using this process. Primarily, acid treating processes were used to improve color, odor, removal/reduction of aromatic content and other undesirable constituents such as polar nitrogen containing compounds and/or some of the trace metals present in the products. Removal of these undesired constituents leads to considerable improvement in physical properties of the treated petroleum / petrochemical product.

Sulfuric acid treating is known to be one of the oldest and best suited treating agent for a large variety of petroleum-related applications. Use of sulfuric acid was widely accepted as an acid treating agent for upgrading petroleum products. Although petroleum refining industry and researchers have used other acids like hydrofluoric acid, hypochlorous acid for treating of the petroleum products, such as lubricating oil, best performance and economics of the operation could be achieved by using sulfuric acid treating only.

In the process, a product is thoroughly mixed with the acid in a mixer and this mixture is allowed to settle for some time for achieving complete phase separation of aqueous and organic layers. Treated product, i.e., upper organic layer is removed and water washed to give the finished product. If still better quality product is desired with further improvement in color and/or removal of polar constituents, this acid treated product layer may be further treated with clay then followed by water washing as per the process requirements. The bottom layer, i.e., acidic

aqueous layer is taken out from the bottom of the settling tank for the recovery of extracted petroleum products and the recycle of the acid for further product treating or dilute acid; if it cannot be used further then this acid is treated with alkali to neutralize it and it is sent to disposal to water treatment plant.

As in the other treating processes in crude oil refining, acid treatment may also be used as a simple single-stage extraction process, or if required, as a complex multi-stage extraction process. The process requirements and treating scheme is designed based on the nature of the product to be treated and extent of product quality improvement requirement.

Pre-treating and post-treating of the products before and after acid treating also plays a significant role in product quality enhancement by acid treating. Whether it should be clay treatment or simple water washing after acid treating, the overall process requirement can be optimized easily depending upon quality requirements of the finished product. As discussed earlier, clay treatment after acid treating further reduces the polar constituents present in the product besides improving the color of the product. If desired product quality is achieved by acid treatment only then clay treatment step is not essential and simple water washing can give the desired product quality.

A number of process-related parameters play significant roles for the optimization of process requirements and these parameters depend upon the extent of refining needed. Acid concentration is the primary and most important of such requirements; generally lower acid concentrations, around 25% or less are used for the treatment of the alkaline sludge generated in various refinery processes, by neutralizing it before its safe disposal to the water treatment plant. Moderate to strong acid requirement are effectively used in polymerization of olefins and diolefins.

Treatment of higher viscosity products require strong acid concentrations. With varying acid concentrations ease of separation of the acid and organic layer can also be achieved. With dilute acids the phase separation is easy as compared to the strong acids. Fuming sulfuric acid is also used for the treatment of the lube oils and the petroleum products. Another process parameter is operating or treating temperature. Temperature also plays a significant role in quality of treatment and subsequently the end product. Other parameters like contact time, numbers of stages, etc., are equally important in the treatment of products.

Disposal of acidic sludge or waste is a serious problem for the refineries. Safe handling of acidic sludge and its disposal is not at all an easy process. Therefore, refineries have avoided acid handling. Older refineries also, which were earlier using acid treating, have also shifted to environmentally safe and less hazardous treating technologies for improving product quality.

See also: Refining.

Acid Value

The acid value (sometimes referred to as the neutralization number, the acid number, or the acidity) is the amount of potassium hydroxide (KOH) in milligrams that is required to neutralize one gram of a chemical substance. It is a measure of the number of carboxylic acid groups in a chemical compound, such as a fatty acid, or in a mixture of compounds.

In a typical procedure, a known amount of sample dissolved in an organic solvent (often an alcohol, such as isopropanol) and titrated with a solution of potassium hydroxide (KOH) of known concentration using an indicator (such as phenolphthalein) to monitor the color change and thereby determine the neutralization point as a colour indicator (see ASTM D664. Standard Test Method for Acid Number of Petroleum Products by Potentiometric Titration).

As an example, the acid number is used to quantify the acidity of a substance such as biodiesel. As oil-fats become rancid, the triglyceride derivatives are converted into fatty acid derivatives and glycerol, thereby causing an increase in acid number. A similar observation is that of biodiesel aging through analogous oxidation processes and when subjected to prolonged high temperatures (ester thermolysis) or through exposure to acids or bases (acid/base ester hydrolysis).

See also: Acidity and Alkalinity, Acid Number, Neutralization Number.

Activated Sludge Process

Activated sludge consists of sludge particles, teeming with living organisms, produced in either raw or settled wastewater by the growth of organisms (which include bacteria) in aeration tanks where dissolved oxygen is present.

In general, sludge is defined on the basis of the solids content (Figure A-1) but in order to develop a quantitative definition of sludge which will also help with correlating waste forms with disposal options, a simple and measurable characteristic of all three waste forms needs to be identified.

<i>Waste form</i>	<i>Solid,</i>	<i>Sludge</i>	<i>Liquid</i>
<i>Total solids, % w/w</i>	50 to 100	1 to 50	<1%

Figure A-1 Simplified distinction between solid waste, sludge, and liquid waste.

Activated sludge processes treat waste streams that contain 1% or less of suspended solids. In this process, flocculated biological growths are continuously circulated in contact with organic wastewater in the presence of oxygen. The process is widely used for industrial wastes and is even more common in municipal treatment plants.

In the process, air or pure oxygen is bubbled through industrial wastewater combined with organisms to develop a biological floc, which reduces the organic content of the wastewater.

The combination of industrial wastewater and biological mass is commonly known as mixed liquor. Once the industrial wastewater has received sufficient treatment, excess mixed liquor is discharged into settling tanks and the treated supernatant liquid is run off to undergo further treatment before discharge. Part of the settled material (sludge) is returned to the head of the aeration system to re-seed the new sewage (or industrial wastewater) entering the tank. Excess sludge which eventually accumulates beyond what is returned is the waste activated sludge which is removed from the treatment process to keep the ratio of biomass to food supplied (wastewater) in balance. The waste activated sludge is stored away from the main treatment process in storage tanks and is further treated by digestion, either under anaerobic or aerobic conditions prior to disposal.

See also: Chemical Waste, Sludge.

Additives – Catalysts in Combustion Systems

Additives may catalyze or otherwise affect combustion processes. For example, salt has long been known to be of some assistance in removing soot deposits from chimneys and the carbonaceous feedstock treated with a more complex mixture of metal oxides has been reported to be activated in combustion systems but it is apparently not resolved whether the catalytic effect is with regard to carbon-oxygen reactions or whether it is more indirect since the effect resembles (to a degree) the catalysis of feedstock-steam systems in which alkali salts serve to catalyze the carbon-steam reaction to produce synthesis gas (carbon monoxide/hydrogen mixtures). This mixture may then, in turn, react to produce hydrocarbons and oxygenated materials in the presence of the multitude of trace metals that can (and do) occur in biomass feedstocks.

In addition to causing objectionable stack emissions, ash and volatile inorganic material generated by thermal alteration of mineral matter in the feedstock will adversely affect heat transfer processes by fouling heat-absorbing and radiating surfaces and will also influence the performance of the combustion system by causing corrosion, and operating procedures must therefore provide for effective countering of all these hazards.

Corrosion is mainly caused by oxides of sulfur, but in certain parts of a combustion system, specifically on furnace wall tubes with metal temperature of 290 to 425°C (550 to 800°F) and superheater or reheater tubes with temperatures in the range 600 to 700°C (1,110 to 1,300°F), corrosion can be induced by tube deposits that destroy protective surface oxide coatings.

Corrosion damage that is usually ascribed to sulfur is actually caused by sulfuric acid, which is generated from organic and inorganic sulfur-bearing compounds:

Oxidation of sulfur dioxide to sulfur trioxide occurs mostly in flames where (transient) atomic oxygen species are thought to be prevalent by interactions of hydrogen atoms with oxygen:

As well as by interactions of carbon monoxide with oxygen:

The process can be catalyzed by the ferric oxides which form on boiler tube surfaces and show excellent catalytic activity for sulfur dioxide oxidation at approximately 600°C (1110°F), i.e., at temperatures which occur in the super-heater section of a boiler.

The presence of water has a marked effect on combustion (by participating in various combustion reactions) and there is evidence for the existence of active centers for chain reactions involved in the further combustion of carbon monoxide and hydrogen (which would be reaction intermediates in the combustion process).

The endothermic steam-carbon reaction is primarily responsible for cooling effects in furnaces and the presence of moisture is believed to cause heat generation at the surface of the bed and in the combustion by virtue of the (endothermic) formation of carbon monoxide and hydrogen in the bed which then burn at the surface. On the other hand, the presence of water vapor appears to assist in the formation of carbon dioxide:

Moisture appears to play a more integral role in the combustion of hydrogen-deficient carbonaceous fuels (such as coal) than has been generally recognized. The carbon-steam reaction to produce carbon monoxide and hydrogen (which are then oxidized to the final products) is an important stage in the combustion sequence as is the carbon monoxide shift reaction to yield carbon dioxide and hydrogen:

Since the whole system involves reaction (and equilibria) between the fuel (i.e., carbon), water, carbon monoxide, hydrogen, and carbon dioxide, the rapid rates of the reactions render it difficult (if not impossible) to determine precisely which of the reactions are the major rate-controlling reactions. In addition, the heterogeneous nature of the system adds a further complication.

The presence of inert gases would usually be expected to dilute the reactants and therefore diminish the reaction rates, such inert materials may actually, on occasion, accelerate the reaction(s). Indeed, the addition of nitrogen to the reaction mixture can be as effective as the addition of oxygen. The nitric oxide formed in the mixture is believed to act as a catalyst:

Additives – Fuels

The term fuel additives applies to chemicals that are intended to improve the capabilities of a gasoline-fuel or diesel-fueled engine while it is running or in use. Fuel stabilizers are designed to keep the fuel in a functional condition when being stored for a long period of time without use. Chemicals may also be added to liquid fuels such as heavy oil and crude shale oil to improve the transportation properties. Pour point depressants have been successful in some instances but are disadvantageous because they only change the physical characteristics of the oil and not its chemical properties.

In modern fuels, a combination of several chemical additives is used in order for the fuel to meet the desired performance level. For example, the use of antiknock additives permits greater efficiency and higher power output because of the higher compression ratios they produce. In certain diesel engines, the higher cetane fuels have shorter ignition delay periods than lower cetane fuels. Several different additives have been tried to increase the cetane number of diesel fuel and lubricity improvers as well as friction modifiers both work through the action of film formation on the metal surfaces. However, biodiesel is, to a point, capable of self-lubricating, thereby reducing friction in diesel engines.

Add-On Environmental Control Methods

There are four general processes used for emission control: (i) adsorption, (ii) absorption, (iii) catalytic oxidation, and (iv) thermal oxidation.

Adsorption is a physico-chemical phenomenon in which the gas is concentrated on the surface of a solid or liquid. Subsequently, the captured gas can be desorbed with hot air or steam either for recovery or for thermal destruction. Usually, activated carbon is the adsorbing medium, which can be regenerated upon desorption. Adsorbers are widely used to concentrate a low gas concentration prior to incineration unless the gas concentration is high in the inlet airstream. Adsorption also is employed to reduce odors from gases which have potential odor problems. The only major limitation for an adsorption system is the requirement for minimization of particulate matter and/or condensation of liquids (e.g., water vapor) that could mask the adsorption surface and drastically reduce its efficiency.

Absorption differs from adsorption in that it is not a physico-chemical surface phenomenon, but an approach in which the absorbed gas is ultimately distributed throughout the absorbent (liquid). The process depends only on physical solubility and may include chemical reactions in the liquid phase (chemisorption). Common absorbing media used are water, caustic, sodium carbonate, and nonvolatile hydrocarbon oils, depending on the type of gas to be absorbed. Usually, gas-liquid contactor designs which are employed are plate columns or packed beds.

Catalytic oxidation is used predominantly for destruction of volatile organic compounds (VOCs) and carbon monoxide, these systems operate in temperature regime of 205 to 595°C (400 to 1100°F) in the presence of a catalyst. Without the catalyst the system would require much higher temperatures to operate. Typically, the catalysts used are a combination of noble metals deposited on a ceramic base in a variety of configurations (e.g., honey-comb-shaped) to enhance good surface contact. Catalytic systems are usually classified based on bed types such as fixed-bed (or packed-bed) and fluid-bed. These systems generally have high destruction efficiencies for most volatile organic compounds, resulting in the formation of carbon dioxide, water, and varying amounts of hydrogen chloride (from halogenated hydrocarbons).

Thermal oxidation systems without the use of catalysts, operate at temperatures in excess of 815°C (1,500°F). These operating temperatures are 220-610°C (395-1100°F) higher than catalytic systems.

Particulate matter control (often referred to as dust control) has been one of the primary concerns of industries, since the emission of particulate matter is readily observed through the deposition of fly ash and soot as well as in impairment of visibility. Differing ranges of control can be achieved by use of various types of equipment. Upon proper characterization of the particulate matter emitted by a specific process, the appropriate piece of equipment can be selected, sized, installed, and performance tested. The general classes of particulate matter control devices are: (i) cyclones: wet, dry, axial flow, multi-cyclones, (ii) fabric filters, (iii) wet scrubbers, and (iv) electrostatic precipitators.

Other than settling chambers for large particles, cyclone-type collectors are the most common of the inertial collector class. The particle-laden gas stream enters an upper cylindrical section tangentially and proceeds downward through a conical section. Particles migrate by centrifugal force to the wall and are removed through a seal at the apex of the inverted cone. A reverse-direction vortex moves upward through the cyclone and discharges through a top center opening. Cyclones are often used as primary collectors because of their relatively low efficiency (50-90% is usual). Some small-diameter high-efficiency cyclones are utilized. Particulate matter is removed by centrifugal forces generated by providing a path for the carrier gas to be subjected to a vortex-like spin. Cyclones are effective in removing coarser fractions of particulate matter. The equipment can be arranged in either parallel or series to both increase efficiency and decrease pressure drop.

Fabric filters are typically designed with non-disposable filter bags. As the dusty emissions flow through the filter media (typically cotton, polypropylene, Teflon, or fiberglass), particulate matter is collected on the bag surface as a dust cake. Fabric filters are generally classified based on the filter bag cleaning mechanism employed and operate with collection efficiencies above 99%.

Wet scrubbers are devices in which a counter-current spray liquid is used to remove particles from an airstream. Device configurations include plate scrubbers, packed beds, orifice scrubbers, venturi scrubbers, and spray towers, individually or in various combinations. Wet scrubbers can achieve high collection efficiencies at the expense of prohibitive pressure drops. These units for particulates operate by contacting the particles in the gas stream with a liquid. In principle, the particles are incorporated in a liquid bath or in liquid particles which are much larger and therefore more easily collected. Other techniques include high-energy input venturi scrubbers, electrostatic scrubbers where particles or water droplets are charged, and flux force/condensation scrubbers where a hot humid gas is contacted with sub-cooled liquid or where steam is injected into saturated gas. In the latter scrubber, the movement of water vapor toward the cold water surface carries the particles with it (diffusiophoresis), while the condensation of water vapor on the particles causes the particle size to increase, thus facilitating collection of fine particles. The foam scrubber is a modification of a wet scrubber in which the particle-laden gas is passed through a foam generator where the gas and particles are enclosed by small bubbles of foam.

Electrostatic precipitators operate on the principle of imparting an electric charge to particles in the incoming airstream, which are then collected on an oppositely charged plate across a high voltage field. The dust cake is then collected from the plate by striking it with rappers. The dust collection efficiency is a strong function of dust resistivity. In general, particles in a gas stream are charged by a high-voltage discharge electrode and collected at collection plates of opposite polarity. Particles of high resistivity create the most difficulty in collection. Because resistivity varies with temperature, this can be an important parameter. Conditioning agents such as sulfur trioxide have been used to lower resistivity. Other important parameters include design of electrodes, spacing of collection plates, minimization of air channeling, and collection-electrode rapping techniques (used to dislodge particles). Techniques under study include high-voltage pulse energization to enhance particle charging, electron-beam ionization, and wide plate spacing. Electrical precipitators are capable of high efficiencies >99% under optimum conditions, but performance is still difficult to predict in new situations.

Adip Process

The Adip process is regenerative amine process for the removal of hydrogen sulfide and carbon dioxide from natural gas, refinery gas, and synthesis gas. The process uses aqueous solutions of the secondary amine, diisopropanolamine, or the tertiary amine, methyl di-ethanolamine. Amine concentrations up to 50% w/w can be applied. Hydrogen sulfide can be reduced to low sulfur levels. The process can also be applied to remove hydrogen sulfide, carbon dioxide, and carbonyl sulfide (COS) from liquefied petroleum gas or natural gas liquid to low levels.

The Adip-X process is a regenerative amine process that is highly suitable for bulk and deep removal of carbon dioxide from gas streams. The process uses aqueous solutions of the tertiary amine, methyl diethanolamine, and an additive.

See also: Gas Cleaning, Gas Processing, Gas Treating.

Adsorption

Adsorption (sometimes referred to as physisorption) is a process that occurs when a gas or liquid solute accumulates on the surface of a solid or a liquid (adsorbent), forming a film of molecules or atoms (*adsorbate*). It is different from absorption, in which a substance diffuses into a liquid or solid to form a solution. Adsorption is the process by which the gas is concentrated on the surface of a solid or liquid to remove impurities; carbon is a common adsorbing medium which can be regenerated upon desorption. The term sorption encompasses both processes, while desorption is the reverse process.

Adsorption differs from absorption in that the adsorption process is not a physical-chemical phenomenon in which the gas is concentrated on the surface of a solid or liquid to remove impurities. Usually, carbon is the adsorbing medium, which can be regenerated upon desorption. The quantity of material adsorbed is proportional to the surface area of the solid, and, consequently, adsorbents are usually granular solids with a large surface area per unit mass. Subsequently, the captured gas can be desorbed with hot air or steam, either for recovery or for thermal destruction.

The number of steps and the type of process used to produce specification-quality gas and liquids most often depend upon the source and makeup of the wellhead production stream. In some cases, several of the steps may be integrated into one unit or operation, performed in a different order or at alternative locations, or not required at all.

If the attractive forces are chemical in nature and result in the formation of a chemical bond between the solid adsorbent and the adsorbed molecules, the adsorption is called chemical adsorption or chemisorption. In the latter case, the removal of the chemisorbed material to regenerate the adsorbent is more difficult and may require chemical techniques to reactivate the spent adsorbent. For this reason, most adsorbents are operated as physical adsorbents with regeneration by reducing pressure, raising temperature, or flushing with solvents. However, even physical adsorbents are often slowly deactivated over many adsorption regeneration cycles by chemisorption due to unknown trace contaminants in either the adsorbent or the feed stream. At some specific deactivation level, the adsorbent must be either reactivated or discarded.

Two general types of adsorbents are commonly used. The first, of which activated carbon is an example, has a low-energy surface and is selective for non-polar molecules. These can be hydrocarbons and other organic compounds of low polarity such as ether derivatives, ketone derivatives, ester derivatives, and halogenated hydrocarbon derivatives. This type of adsorbent is useful for recovery of organic materials from wastewaters and exhaust gases. The other type of adsorbent, which consists of activated clay minerals, alumina minerals, and silica gel, has a higher energy surface that is more selective for polar molecules.

These materials are usually not effective for water solutions because the water selectively covers all the adsorption sites to the exclusion of everything else. However, they do find use for removing polar impurities such as water, oxidation products, or naturally occurring impurities like sulfur and nitrogen compounds from organic process streams. They are also useful for cleaning slightly contaminated waste streams to permit recycling of the major components. Zeolites and molecular sieves are special cases which depend on pore size and structure, i.e., access to the internal surface, for their selectivity rather than on adsorbent surface energy. They can be made from specially treated carbons as well as from natural or synthetic crystalline materials.

Adsorption Isotherm

The adsorption process is studied through the development of an *adsorption isotherm* which relates the amount of adsorbate (x) adsorbed on the surface of adsorbent (m) and pressure at constant temperature. Different adsorption isotherms have been developed by Freundlich, Langmuir, and by means of the Brunauer, Emmett, and Teller (BET) theory. Simply, the adsorption process can be represented as:

Freundlich Adsorption Isotherm

Freundlich gave an empirical expression representing the isothermal variation of adsorption of a quantity of gas adsorbed by unit mass of solid adsorbent with pressure:

$$\frac{x}{m} = kP^{\frac{1}{n}}$$

In this equation, x is the mass of the gas adsorbed on mass, m , of the adsorbent at pressure p ; k and n are constants whose values depend upon adsorbent and gas at particular temperature. This isotherm establishes the relationship of adsorption with lower pressures but is not always suitable for high-pressure situations.

Langmuir Adsorption Isotherm

The *Langmuir adsorption isotherm* is based on several assumptions, one of which is that dynamic equilibrium exists between adsorbed gaseous molecules and the free gaseous molecules:

In this equation, $A(g)$ is the unadsorbed gaseous molecule, $B(s)$ is unoccupied metal surface, and AB is adsorbed gaseous molecule from which a relationship between the number of active sites of the surface undergoing adsorption and pressure can be derived:

$$\theta = \frac{KP}{1 + KP}$$

Here, θ is the number of sites of the surface which are covered with gaseous molecule, P is the pressure, and K is the equilibrium constant for distribution of adsorbate between the surface and the gas phase. However, the Langmuir adsorption equation is that it is valid at low pressure only. At lower pressure, KP is small and the factor $1 + KP$ in denominator is close to unity which reduces the Langmuir equation to:

$$\theta = KP$$

At high pressure, KP is large and the factor $1 + KP$ is almost equal to KP , thereby reducing the Langmuir equation to:

$$\theta = \frac{KP}{KP} = 1$$

BET Adsorption Isotherm

The BET theory equation invokes the concept that under the condition of high pressure and low temperature, the thermal energy of gaseous molecules decreases and more and more gaseous molecules would be available per unit surface area. As a result, multilayer adsorption will occur and can be represented by the BET equation:

$$V_{total} = \frac{V_{mono} C \left(\frac{P}{P_0} \right)}{\left(1 - \frac{P}{P_0} \right) \left(1 + C \left(\frac{P}{P_0} \right) - \frac{P}{P_0} \right)}$$

Another form of the BET equation is:

$$\frac{P}{V_{total}(P - P_0)} = \frac{1}{V_{mono}C} + \frac{c-1}{V_{mono}C} \left(\frac{P}{P_0} \right)$$

In these equations, V_{mono} is the adsorbed volume of gas at high pressure conditions so as to cover the surface with a unilayer of gaseous molecules. Thus:

$$C = K_1/K_L$$

$$\frac{K_1}{K_L}$$

K_1 is the equilibrium constant when a single molecule is adsorbed per vacant site and K_L is the equilibrium constant to the saturated vapor liquid equilibrium.

See also: Adsorption, Adsorption Process.

Adsorption Process

Adsorption is a physical-chemical phenomenon in which the gas is concentrated on the surface of a solid or liquid to remove impurities. Typically, carbon is the adsorbing medium, which can be regenerated upon desorption, and the quantity of material adsorbed is proportional to the surface area of the solid. Consequently, adsorbents are usually granular solids with a large surface area per unit mass. Subsequently, the captured gas can be desorbed with hot air or steam, either for recovery or for thermal destruction.

Adsorbers are widely used to increase a low gas concentration prior to incineration unless the gas concentration is high in the inlet air stream. Adsorption is also employed to reduce problem odors from gases. There are several limitations to the use of adsorption systems, but it is generally felt that the major one is the requirement for minimization of particulate matter and/or condensation of liquids (e.g., water vapor) that could mask the adsorption surface and drastically reduce its efficiency. Absorption differs from adsorption, in that it is not a physical-chemical surface phenomenon, but an approach in which the absorbed gas is ultimately distributed throughout the absorbent (liquid). The process depends only on physical solubility and may include chemical reactions in the liquid phase (chemisorption). Common absorbing media used are water, aqueous amine solutions, caustic, sodium carbonate, and nonvolatile hydrocarbon oils, depending on the type of gas to be absorbed. Usually, the gas-liquid contactor designs that are employed are plate columns or packed beds.

Separation by adsorption chromatography essentially commences with the preparation of a porous bed of finely divided solid, the adsorbent. The adsorbent is usually contained in an open tube (column chromatography). The sample is introduced at one end of the adsorbent bed and induced to flow through the bed by means of a suitable solvent. As the sample moves through the bed, the various components are held (adsorbed) to a greater or lesser extent depending on the chemical nature of the component. Thus, those molecules that are strongly adsorbed spend considerable time on the adsorbent surface rather than in the moving (solvent) phase, but components that are slightly adsorbed move through the bed comparatively rapidly.

Numerous factors randomly affect the process of migration through a bed, and in fact, the total distance traveled in a given time by different molecules of the same material is not constant. Nevertheless, the suitable choice of a bed and a moving (solvent) phase allows adequate separation of even multi-component mixtures to be achieved.

Adsorption processes for water treatment are used to remove dissolved metals, organic compounds, and many toxic substances. Carbon which has been *activated* (oxidized at high temperatures) to create millions of minute cavities is an effective and economical means of adsorbing dissolved organic and other chemicals that cannot be removed by filtration.

Granular activated carbon and activated carbon black are used in combination with filtration and/or disinfection to remove undesirable tastes and odors, chloramines, some pesticides and herbicides, and other chemical contaminants. They are sometimes also combined with halogen-based disinfection technologies to remove residual iodine and chlorine. Activated carbon does not remove salts.

Adsorption with regenerated carbon slurries and with resin particles is common, and some systems use activated carbon particles that are contained in a fixed bed, either without regeneration or with regeneration within the column. In all cases, the separation involves physical adsorption of the contaminants on the surfaces of the particulate medium.

See also: Adsorption, Adsorption Isotherm, Gas Cleaning, Gas Processing, Gas Treating.

Advanced Cycloning

Advanced cycloning processes involve the separation of two species of different densities using a medium of an intermediate density to the two species. In the process, the heavy mineral matter component of the coal is separated from its lighter organic matter counterpart. Advanced cycloning technology seeks to extend the density-based separating principle to fine and ultrafine coal through the use of alternative media, such as heavy liquids and micronized magnetic, and through the application of centrifugal force to accelerate the separation process.

The dense medium is generally a suspension of fine, high-density particles (magnetite or sand) with the density of the medium varying directly with the solids concentration. The separating performance and downstream recovery of the dense medium suspension require that the difference in size between dense medium particles (magnetite) and coal particles be significant.

See also: Cyclone Separation, Gas Cleaning, Gas Processing, Gas Treating.

Advanced Flue Gas Desulfurization

Flue gas desulfurization (FGD) is the technology used for removing sulfur dioxide (SO_2) from the exhaust flue gases in power plants that burn coal to produce steam for the steam turbines which, in turn, drive the electricity generators. Sulfur dioxide is responsible for acid rain formation. Tall flue gas stacks disperse the emissions by diluting the pollutants in ambient air and transporting them to other regions. However, such practices do not always remove the pollutants.

Advanced flue-gas desulfurization processes remove acid gas from combustion systems burning coal without expensive scrubbers. Emissions are piped into an absorber, where the acid gases react with an absorbing solution (such as a mixture of lime, water, and oxygen). In the process, the gas is usually passed through a particulate removal unit (such as an electrostatic precipitator) after which the flue gas is increased in pressure and then cooled from approximately 130°C (265°F) to 80°C (175°F). It enters the lowest part of the absorber and is further cooled by water used to wash the inlet duct to prevent a buildup of solids.

The main sulfur dioxide absorption process occurs as the gas is scrubbed by a recirculating limestone slurry. This is taken from the bottom of the absorber and is sprayed downwards from nozzles arranged at five separate levels in the absorber tower. As a result of the process chemistry, the recirculating slurry becomes predominantly gypsum (CaSO_4) and a portion is continuously pumped away for gypsum separation and the removal of water using a hydrocyclone system. A wastewater treatment plant ensures that any water from the flue gas desulfurization process returned to the environment meets quality standards set by the regulatory authority.

See also: Flue Gas, Gas Cleaning, Gas Processing, Gas Treating.

Aerobic Digestion

Aerobic digestion is a bacterial process occurring in the presence of oxygen. Under aerobic conditions, bacteria rapidly consume organic matter and convert it into carbon dioxide. Once there is a lack of organic matter, bacteria die

and are used as food by other bacteria. This stage of the process is known as *endogenous respiration*. Solids reduction occurs in this phase.

Composting is also an aerobic process that involves mixing the wastewater solids with sources of carbon such as sawdust, straw, or wood chips. In the presence of oxygen, bacteria digest both the wastewater solids and the added carbon source and, in doing so, produce a large amount of heat.

In an aerobic system, such as composting, the microorganisms access free, gaseous oxygen directly from the surrounding atmosphere. The end products of an aerobic process are primarily carbon dioxide and water which are the stable, oxidized forms of carbon and hydrogen. If the biodegradable starting material contains nitrogen, phosphorus, and sulfur, the end products may also include their oxidized forms: nitrate (NO_3^-), phosphate (PO_4^{2-}), and sulfate (SO_4^{2-}). In an aerobic system, the majority of the energy in the starting material is released as heat by their oxidation into carbon dioxide and water.

Composting systems typically include organisms such as fungi that are able to break down lignin and cellulose to a greater extent than anaerobic bacteria. It is possible, following anaerobic digestion, to compost the anaerobic digestate, allowing further volume reduction and stabilization. When considering an overall system energy and carbon balance, anaerobic digestion performs better than the main alternative, composting.

The aerobic digestion process was initially used in designs for new plants that normally treated waste activated sludge from treatment systems that did not contain a primary settling process; only waste activated or trickling filter sludge, or mixtures of waste activated or trickling filter sludge. Typically, if a primary settling process was incorporated to the design, anaerobic digestion was the process of choice because reliable techniques to thicken and aerobically digest higher than 4% solids were not established at the time.

Because of tighter effluent standards for both nitrogen and phosphorus being enforced in the United States in the late 1990s, primary clarifiers have slowly been eliminated from the process train to preserve a good carbon-to-nitrogen ratio typically required to achieve successful biological nitrogen removal.

As a result of the combination of the new effluent limits and new techniques that provided the capabilities to control aerobic digestion processes and accurately predict the performance of the system, aerobic digestion has become attractive once again. A number of anaerobic digesters have been converted to aerobic digesters because of their relatively easy operation, lower equipment cost, and because they can produce a better quality supernatant with lower nitrates and phosphorus, therefore, protecting the liquid side upstream. An additional benefit of aerobic digestion is the fact that they can achieve comparable volatile solids reduction with shorter retention periods, they have less hazardous cleaning and repairing tasks, and, typically, do not produce an explosive digester gas.

Anaerobic digestion of animal waste is the primary cause of odors, solids buildup and many diseases in swine, dairy and poultry facilities, processing plants, municipal waste systems, and septic systems. Animal waste concentrated in pits under slatted floors or collected in holding tanks or lagoons has the natural tendency to “go anaerobic.” Anaerobic digestion occurs when the anaerobic microbes are dominant over the aerobic microbes. Anaerobic microbes will naturally become dominant in pits or lagoons because of the lack of oxygen in solutions containing heavy concentrations of animal waste, which results in a high biological oxygen demand (BOD). These microbes feed on the animal waste at the bottom of the pits and lagoons. As they digest waste, large amounts of toxic gases are released due to the digestion processes common to the anaerobic microbes.

The anaerobic digestion of animal waste can be changed to aerobic digestion by proper applications of beneficial aerobic microbes in a highly concentrated form. If aerobic microbes are introduced into an environment that is lacking oxygen, they will begin to build oxygen into this environment as long as they survive and reproduce. Aerobes have the ability to do this in a liquid media or in the soil as long as there is an adequate moisture and food source for them to feed on and reproduce.

Once the aerobic microbes become dominant, the aerobic digestion of waste begins. Aerobic digestion, unlike anaerobic digestion, does not produce the pungent gases. The aerobic process results in a more complete digestion of waste solids, reducing the buildup in pits and lagoons by more than 50% in most cases. The aerobic process also improves the environment of the workers and the animals and helps to keep pathogens in check. With proper application, the anaerobic process is converted to aerobic and overall production cost will be reduced.

Aerosols

An aerosol is a suspension of tiny particles or droplets in the air, such as dust, mist, or fumes. These particles may be inhaled or absorbed by the skin, and can sometimes cause adverse health effects for humans. The aerosol particles can be from natural sources or from anthropogenic sources such as the use of various (gaseous, liquid, or solid) fuels, whether the fuels are from fossil fuel sources or from renewable energy sources such as biomass or waste. Aerosol particles – from whatever the source – play an important role in the climate system because of their direct interaction (absorption and scattering) with solar and terrestrial radiation, as well as through their influence on cloud processes and thereby, indirectly, on radiative fluxes.

The particle size of an aerosol is often determined by the process that generated the particle. Combustion particles usually start out in the range 0.01 to 0.05 micron but combine with each other (agglomerate) to form larger particles. Powder is broken down into smaller particles and released into the air; it is difficult to break down such particles smaller than 0.5 micron. Biological particles usually become airborne from liquid or powder forms, so these particles are usually larger than 0.5 micron.

Aerosol emissions (often collectively classed as particulate matter) from stationary combustion sources burning renewable fuels such as biomass, and waste are a significant source of primary particles smaller than 2.5 microns (often written as $PM_{2.5}$) in urban areas. Combustion-generated particles are generally smaller than geologically produced dust and have unique chemical composition and morphology. The emission of particle matter that contains transition metals, ultrafine particles, and soot are controlled by the fuel composition and the oxidant-temperature-mixing history from the flame to the stack. Particle surface area, number of ultrafine particles, bioavailable transition metals, polycyclic aromatic hydrocarbon derivatives (PAH, also referred to as polynuclear aromatic hydrocarbon derivatives, PNAs), and other particle-bound organic compounds are important than particle mass in determining the effects of air pollution. Wood smoke forms when wood is combusted and is made up of a complex mixture of gases and fine particles (particulate matter, PM). In addition to particle pollution, wood smoke contains several toxic harmful air pollutants including benzene, formaldehyde, acrolein, and polycyclic aromatic hydrocarbon derivatives.

Aerosol particles have a lifetime of up to several weeks in the troposphere and occur in highly variable concentrations. A large proportion of the particles that influence cloud processes and the radiative balance is derived from gaseous sulfur-containing emissions.

Agave Bagasse

Bagasse is the fibrous residue remaining after sugarcane or sorghum stalks are crushed to extract their juice and is currently used as a renewable resource in the manufacture of pulp and paper products and building materials. Bagasse is a heterogeneous material containing approximately 30-40% w/w of pith fiber, which is derived from the core of the plant and is mainly parenchyma material, and rind or stem fiber, which makes up the balance of the material. Bagasse is often used as a primary fuel source for sugar mills. When burned in quantity, it produces sufficient heat energy to supply all the needs of a typical sugar mill, with energy to spare. In addition, a secondary use for this waste product is in cogeneration, the use of a fuel source to provide both heat energy, used in the mill, and electricity, which is typically sold on to the consumer electrical grid.

Agave plants are used for fiber (henequén) production in the Yucatan peninsula for tequila and mezcal production in southern, west-central, and western Mexican states; and also for producing a traditional fermented beverage called pulque, in the highlands of central plateau of Mexico, including agricultural areas within the limits of Mexico City. The agave bagasse consists of the tissue of the blue agave after extraction of the sap. It is the residual fiber from slaughterhouses remaining after cooked agave heads are shredded and milled and the sugars are water-extracted. The bagasse is primarily the rind and fibrovascular bundles dispersed throughout the interior of the agave head.

The availability and characteristics of agave bagasse including structure, fiber size, and absorbency suggest that agave bagasse would be a suitable bulking agent for composting and to determine a viable method for the biodegradation of waste by piling alternate layers of offal with agave bagasse as a bulking agent.

See also: Bagasse, Biomass.

Agricultural Residue

Agricultural residues, which are a convenient renewable energy source, include straw, manure, vegetables, as well as fruit waste and general garden waste (Table A-5). Other residues include potatoes and sugar beet tops as well as damaged fruit and nursery wastes, and use of agricultural waste reduces the possibilities for odor and water pollution by manure. Aside from their abundance and renewability, using agricultural residues will benefit farmers, industry, and human health and the environment.

Table A-5 Examples of the Types and Bulk Composition of Agricultural Residues.

Agricultural residue	Cellulose	Hemicellulose	Lignin
Bagasse (sugar cane)	32-48	19-24	23-32
Bamboo	41-49	24-28	24-26
Cattle manure	1.6-4.7	1.4-3.3	2.7-5.7
Coastal Bermuda grass	25	35.7	6.4
Corn cobs	45	35	15
Corn stover	35	28	16-21
Grasses	25-40	35-50	10-30
Leaves	15-20	80-85	0
Nut shells	25-30	25-30	30-40
Pig waste	6.0	28	-
Rice straw	40	18	5.5
Sorghum (sweet)	27	25	11
Sorted refuse	60	20	20
Switch grass	30-51	10-50	5-20
Wastewater solids	8-15	NA	24-29
Wheat straw	33-40	20-25	15-20
Wood (hardwood)	40-50	24-40	18-25
Wood (softwood)	45-50	25-35	25-35

For example, until recently the excess straw produced was generally burned in the fields or ploughed back into the land. However, the environmental legislation put in place in many countries has restricted field burning and straw has been seen as a potential source of energy.

Dry residues include those parts of arable crops (such as corn stover, straw, and poultry litter) not to be used for the primary purpose of producing food, feed, or fiber, used in animal bedding and feathers. On the other hand, wet residues (which are residues and wastes that have a high water content as collected) include (i) animal slurry, (ii) farmyard manure, and (iii) grass silage.

Agriculture residues directly burned as fuel in the developing world include crop residues, forest litter, and also grass and animal garbage. Crop residues are more widely burnt than animal waste and forest litter. Crop residues encompass all agricultural wastes such as straw, stem, stalk, leaves, husk, shell, peel, lint, stones, pulp, stubble, etc. which come from cereals (rice, wheat, maize or corn, sorghum, barley, millet), cotton, groundnut, jute, legumes (tomato, bean, soy), coffee, cacao, olive, tea, fruits (banana, mango, coco, cashew), and palm oil.

Because agricultural residues are of a wide variety of types, the most appropriate energy conversion technologies and handling protocols vary from type to type. The most significant division is between those residues that are predominantly dry (such as straw) and those that are wet (such as animal slurry). Many agricultural crops and processes yield residues (Table A-6) that can potentially be used for energy applications, in a number of ways. Sources can include: (i) arable crop residues such as straw or husks, (ii) animal manures and slurries, and (iii) animal bedding such as poultry litter.

Table A-6 Examples of crops and crop wastes.

Crops	Crop wastes
Barley	Straw, bran
Coco	Hull, fiber
Coffee	Pulp, husk
Cotton	Stalk, lint, hull
Groundnut	Shell, stalk, leaves
Jute	Stem
Maize	Stalk, leaves
Mango	Peel
Millet	Straw, bran
Palm oil	Shell, fiber, fruit bunches
Rice	Straw, husk, bran
Sorghum	Straw, bran
Tomato	Stem
Wheat	Straw, husk, bran

Forest litter is mainly constituted of dry fallen leaves. Plantations of those species widely used for reforestation or soil conservation/sand fixation such as *Eucalyptus* and *Casuarina equisetifolia*, provide an important biomass litter yearly. Animal garbage is livestock manure. Generally, dry animal wastes directly used as fuel are cow and camel dung, and sometimes that of horse and sheep. The quantity of manure produced depends on the amount of fodder eaten, the quality of fodder, and the live weight of the animal. The excrement-yield values vary among the species.

In many developing countries, most agricultural residues burned as fuel are used in their natural state with some pre-treatment like drying, and cutting, and compacting in rare occasions. Crop residues are characterized by its seasonal availability and have characteristics that differ from other solid fuels such as wood, charcoal, and char briquette. The main differences are the high content of volatile matter and lower density and burning time.

The moisture content make wet residues energetically inefficient to use for combustion or gasification. It is preferable to process them close to production, and to use processes that can make use of biomass in an aqueous environment. Any moisture content must be driven off before processing (such as combustion) can take place, either in advance before storage or as part of the combustion process (which then uses part of the energy of the fuel). Gasification also requires relatively low moisture content (<10-15%).

Many of the above agricultural residues may have alternate uses or markets, and any decision to use them for energy must be made in the context of these renewable sources. In particular, many such residues are presently widely used for soil nutrient recycling and improvement purposes and may therefore be displacing significant quantities of synthetic fertilizers or other products. As the manufacture of many of these products entails significant carbon dioxide emissions and energy inputs, their substitution for agricultural residues should not be undertaken without caution.

See also: Agricultural Waste, Biomass, Residues, Rice Straw, Wheat Straw.

Agricultural Residue – Types

The four main types of agricultural residues are (i) feed and seed crop, (ii) fruit and nut crop, (iii) vegetable crop, and (iv) nursery crop and vary in composition (Table A-7).

Table A-7 Properties of various agricultural residues.

Agricultural residues	Volatiles (%)	Fixed carbon (%)	Ash (%)	HHV (Kj/kg)	LHV (Kj/kg)	Density (%)
Arhar stalk	83.47	14.76	1.77	15.00	14.85	
Bagasse	75.10	16.87	8.03	19.50	19.37	40 – 60
Bamboo dust	75.32	15.59	9.09	16.02	15.87	
Cotton stalk	70.89	22.43	6.68	18.26	17.85	10 – 20
Coconut coir	70.30	26.77	2.93	18.20	17.79	7 – 8
Corn cob	80.20	16.20	3.60	15.58	15.23	10 – 20
Dhaincha stalk	80.32	17.01	2.67	19.63	19.43	
Groundnut shell	68.12	24.97	6.91	17.20	17.06	
Jute stick	75.33	19.00	5.67	19.45	19.01	
Mustard shell	70.09	14.48	15.43	17.61	17.47	
Pine needle	72.38	26.12	1.50	20.12	19.97	
Rice husk	60.64	19.90	19.48	13.38	13.24	9
Sal seed leaves	60.03	20.22	19.75	18.57	18.42	
Sal seed husk	62.54	28.06	9.40	20.60	20.13	

Field and seed crop residues are the materials remaining above the ground after harvesting, including straw or stubble from barley, beans, oats, rice, rye, and wheat, stalks, or stover from corn, cotton, sorghum, soybeans, and alfalfa. The moisture content (wet basis) of these residues ranges from 8 to 80%. The typical bulk density of loose straw and stover varies from 1 to 3 lb/ft³ and the bulk density of baled straw and stover varies from 7 to 12 lb/ft³. If pelletized, the bulk density increases to 35 to 45 lb/ft³.

Fruit and nut crop residues include orchard pruning residues and brushes. The types of fruit and nut crops include almonds, apples, apricots, avocados, cherries, dates, figs, grapefruit, grapes, lemons, limes, olives, oranges, peaches, pears, plums, prunes, and walnuts. The moisture content (wet basis) of these residues ranges from 35 to 55%. Hammer-milled orchard pruning residues have a bulk density of from 9 to 12 lb/ft³.

Vegetable crop residues consist mostly of vines and leaves that remain on the ground after harvesting. The types of vegetable crops include such plants as artichokes, asparagus, cucumbers, lettuce, melon, potatoes, squash, and tomatoes. The moisture content (wet basis) of these residues is usually greater than 90%.

Nursery crop residues include the pruning residues and trimmings taken from the plants during their growth and in the preparation for market. There are more than 30 different species of nursery crops (such as flowers and indoor plants) that are grown. The moisture content of these residues is usually dependent on the type of crop that is being grown.

Quantifying the amounts and types of agricultural residues generated in each of the crop categories is extremely difficult, as it would require conducting comprehensive research throughout the state with continuous updates to the compiled data. Without ongoing data collection, any quantification estimates would only be valid for the time frame that the study was done and would be susceptible to ongoing market changes. Any quantification of agricultural residue tonnages should be viewed with these inherent limitations in mind and the tonnages quoted should not be considered absolute values.

Agricultural Waste

Agricultural waste is the waste material remaining after processing crops to a marketable material or as a result of various agricultural operations. Agricultural wastes, which may include horticultural and forestry wastes, comprise crop residues, animal manure, diseased carcasses, as well as other wastes from farms, poultry houses and slaughterhouses, harvest waste, fertilizer run-off from fields, pesticides that enter into water, air, or soil; and salt and silt drained from fields.

The composition depends on the system of agriculture. Estimates of agricultural wastes are rare, but they are generally thought of as contributing a significant proportion of the total waste matter in the developed world. Since 1960, as a result of huge rises in productivity, there have been corresponding increases in the volumes of crop residues and animal manure requiring disposal. There is likely to be a significant increase in agricultural wastes globally if developing countries continue to intensify farming systems.

Agricultural wastes include both natural (organic) and non-natural waste materials. The main non-natural wastes include packaging, non-packaging plastics (such as silage and horticultural films); agrochemicals; animal health products (such as used syringes); waste from machinery (such as oil, tires, and batteries) and building waste (such as asbestos sheeting). Common wastes are sugar cane bagasse and cotton gin trash. Many agricultural wastes are sold as animal feed and materials unsuitable for use as animal feed are typically burned on site as fuel, thereby giving some processing plants the potential for being self-sufficient in energy.

See also: Agricultural Residues, Residues, Rice Straw, Wheat Straw.

Agrofuel

An agrofuel is a type of biofuel which is solid, liquid, or gaseous fuel and is obtained from relatively recently lifeless or living biological material. An agrofuel is a fuel that is obtained as a product of agriculture biomass and by-products at farming level, and/or industrial processing of raw material (agro-industries). The term covers mainly biomass materials derived directly from fuel crops and agro-industrial and animal by-products (Table A-8).

The three main types of biofuel are: (i) agrofuels, (ii) wood fuels, and (iii) municipal waste (sometime referred to as municipal by-products) which include gas, liquid, and solid products derived from processing activities (Table A-8) in which the major consideration is to identify the basic site where biomass production takes place. It is often necessary to distinguish whether the biofuel was connected to forest, agricultural, or municipal activities. The inclusion of a group on the use of agrofuels aims at distinguishing classical biofuels (generally related to forest exploitation) from those oriented toward annual or pluri-annual plantation.

Table A-8 Types of renewable fuel sources and products.

Source	Phase	Products
Agrofuels	Gas	Biogas, producer gas, pyrolysis gas from agrofuels
	Liquid	Ethanol, vegetable oil, methanol, pyrolysis oil
	Solid	Straw, stalks, husks, bagasse, charcoal
Woodfuels	Gas	Products from gasification and pyrolysis gases
	Liquid	Black liquor, methanol, pyrolysis oil
	Solid	Fuelwood (chips, sawdust, pellets), charcoal
Municipal waste	Gas	Landfill gas, sludge gas
	Liquid	Sewage sludge, pyrolysis oil
	Solid	Municipal solid waste

Another term – agrifuel – also referred to a fuel produced directly from crops and other agricultural sources. The term is also more generally applied to organic matter, converted to transportation fuels that reduce the use of imported oil and are more environmentally friendly.

Biodiesel is also an agrifuel that is blended with or replaces crude oil diesel. With biodiesel, any diesel engine can become a renewable fuel engine. Biodiesel is made in the USA from vegetable oils, animal fats, and used restaurant grease. Biodiesel is safer to use, handle, and store than crude oil diesel and is less environmentally damaging to produce, cleaner at the tailpipe (lower emissions), and less damaging if it spills on the ground or in water.

In addition, agricultural biodiesel (agri-biodiesel, agribiodiesel) is biodiesel produced from virgin vegetable oils derived from corn, soybeans, sunflower seeds, canola, cottonseeds, rapeseeds, safflowers, flaxseeds, rice bran, and mustard seeds, as well as from animal fats.

See also: Agrofuel, Biodiesel.

Air Emissions

Air emissions can arise from any one of several sources in any energy production plant, including: (i) combustion emissions associated with the burning of fuels, including fuels used in the generation of electricity, (ii) equipment leak emissions, which are also referred to (fugitive emissions) released through leaking valves, flanges, pumps, or other process devices, (iii) process vent emissions, which are also referred to as (point source emissions) released from process vents during manufacturing, (iv) storage tank emissions released when products are transferred to and from storage tanks, and (v) wastewater system emissions from tanks, ponds, and sewer system drains.

The numerous process heaters used in refineries to heat process streams or to generate steam (boilers) for heating or steam stripping, can be potential sources of sulfur oxides (SO_x), nitrogen oxides (NO_x), carbon oxides (CO, CO₂), particulate matter, and volatile organic compounds, VOCs). When operating properly and when burning cleaner fuels such as natural gas, fuel gas, fuel oil, and process gas, these emissions are relatively low.

The three main greenhouse gases that are products of the various processes are carbon dioxide, nitrous oxide, and methane. Carbon dioxide is the main contributor to climate change. Methane is generally not as abundant as carbon dioxide but is produced during refining and, if emitted into the atmosphere, is a powerful greenhouse gas and more effective at trapping heat. However, gaseous emissions associated with biomass conversion to fuels typically include process gases, volatile organic compounds (VOCs), carbon monoxide (CO), sulfur oxides (SO_x), nitrogen oxides (NO_x), particulates, ammonia (NH₃), and hydrogen sulfide (H₂S). These effluents may be discharged as air emissions and must be treated. However, gaseous emissions are more difficult to capture than wastewater or solid waste and, thus, are the largest source of untreated wastes released to the environment.

In addition to the corrosion of equipment by acid gases, the escape into the atmosphere of sulfur-containing gases can eventually lead to the formation of the constituents of acid rain, i.e., the oxides of sulfur (SO₂ and SO₃). Similarly, the nitrogen-containing gases can also lead to nitrous and nitric acids (through the formation of the oxides NO_x, where x = 1 or 2) which are the other major contributors to acid rain. The release of carbon dioxide and hydrocarbons as constituents of refinery effluents can also influence the behavior and integrity of the ozone layer.

Emissions from the sulfur recovery unit typically contain some hydrogen sulfide (H₂S), sulfur oxides, and nitrogen oxides. Other emissions sources from refinery processes arise from periodic regeneration of catalysts. These processes generate streams that may contain relatively high levels of carbon monoxide, particulates, and volatile organic compounds (VOCs). Before being discharged to the atmosphere, such off-gas streams may be treated first through a carbon monoxide boiler to burn carbon monoxide and any volatile organic compounds, and then through an electrostatic precipitator or cyclone separator to remove particulates.

The processes that have been developed to accomplish gas purification vary from a simple once-through wash operation to complex multi-step recycling systems. In many cases, the process complexities arise because of the need for recovery of the materials used to remove the contaminants or even recovery of the contaminants in the original, or altered, form.

Air Emissions – Biomass Plant

Biomass power plant emissions will be different from emissions from a coal-based power plant because biomass is lower in sulfur than most US coals. Typical biomass contains 0.05 to 0.20% w/w sulfur on a dry basis. In comparison, coal has 2 to 3% w/w sulfur on a dry basis. The biomass sulfur content translates to approximately 0.12 to 0.50 lb SO₂/MMBtu. Because of this, burning biomass to generate power typically produces less SO₂ emissions than using coal.

NO_x emissions should usually be lower for biomass than for coal, due to lower fuel nitrogen (N) content and due to the higher volatile fraction of biomass versus coal. However, this difference may not have much influence on the selection of the technology (i.e., coal or biomass) because the compliance costs are relatively insignificant given the small difference in NO_x emissions.

Biomass power production can result in large emissions of carbon dioxide (CO₂). Sometimes, biomass combustion results in larger emission values than for fossil fuels because of the lower combustion efficiencies. However, because the carbon dioxide released by combustion was removed from the atmosphere in the recent past through photosynthesis and new plant growth will continue to remove carbon dioxide from the atmosphere after biomass is harvested, it is sometimes argued that biomass is carbon dioxide neutral.

However, in practice, the issue is more complicated since other carbon flows are involved, including carbon dioxide emissions associated with fossil fuel used in harvesting, processing, and transportation operations. Although it is certain that the net amount of carbon dioxide emitted from a biomass power plant is less than a fossil power plant, it must be recognized that under current production practices, biomass power is not a net zero carbon dioxide process.

Biomass combustion device emissions are estimated on a site-specific basis to determine whether a particular location is appropriate for developing a facility. In many cases, data specific to a particular wood-burning appliance are not readily available. However, the United States Environmental Protection Agency provides emission factors that can be used to estimate emissions from wood-fired boilers as part of efforts to estimate the effects of specific combustion sources and determine the applicability of relevant permitting programs.

See also: Acid Rain, Air Emissions.

Air Flotation Processes

Air flotation processes are even more effective but are relatively complex. In the dissolved air flotation cell, air is injected into the oily wastewater as fine bubbles. The oil droplets adhere to the air bubbles and rise to the surface as a froth, which is skimmed off by a motor-driven rake. Some small, suspended particulate contaminants can also be removed in the froth, and others will settle to the bottom of the cell and can be removed as sludge. A coagulant can also be added to aid removal efficiency. If lime is added, for example, it will precipitate some heavy metals and certain anions such as carbonates.

Dissolved air flotation is a water treatment process that clarifies wastewaters (or other waters) by the removal of suspended matter such as oil or solids. The removal is achieved by dissolving air in the water or wastewater under pressure and then releasing the air at atmospheric pressure in a flotation tank or basin. The released air forms tiny bubbles which adhere to the suspended matter, causing the suspended matter to float to the surface of the water where it may then be removed by a skimming device.

Dissolved air flotation is very widely used in treating the industrial wastewater effluents from oil refineries, petrochemical and chemical plants, and natural gas processing plants and could find use in the oil shale industry.

See also: Settling and Flotation.

Air Pollution

The term air pollution refers to the release of pollutants into the air that are detrimental to human health and the planet as a whole. Air pollution arises from energy use and production and not only from the use of fossil fuels but also from the use of fuels from renewable sources and also from natural events (using volcanoes as the example of a natural event). Air pollution may cause diseases, allergies, and even death to humans as well as cause harm to other living organisms such as animals and food crops, and may damage the environment.

Smog and soot are the most prevalent types of air pollution. The former (smog) occurs when emissions from the combustion of fuels (including biomass and other renewable fuel sources) react with sunlight. Soot (particulate matter) is composed of small (often micron-size) particles of chemicals, soil, smoke, dust, or allergens, in the form of gas or solids, that are carried in the air. Smog can irritate the eyes and throat and also damage the lungs – especially of people who work or exercise outside and is even worse for people who have asthma or allergies – the pollutants only intensify their symptoms and can trigger asthma attacks.

Hazardous air pollutants are either deadly or have severe health risks even in small amounts and most often emitted during gas or combustion of other fossil fuels and fossil fuel products. Polycyclic aromatic hydrocarbon derivatives are toxic components of traffic exhaust and wildfire smoke. In large amounts, they have been linked to eye and lung irritation, blood and liver issues, and even cancer. Dioxin derivatives are also present in small amounts in the air and can affect the liver in the short term and harm the immune, nervous, and endocrine systems, as well as reproductive functions.

Mold and allergens from trees, weeds, and grass are also carried in the air, are exacerbated by climate change, and can be hazardous to health. They are not regulated by the government and are less directly connected to human actions, but they can be considered air pollution. When homes, schools, or businesses are subject to water damage, mold can grow and can produce allergenic airborne pollutants. Exposure to mold can precipitate asthma attacks or an allergic response, and some molds can even produce toxins that would be dangerous for anyone to inhale. Pollen allergies are worsening because of climate change which extends the pollen production season.

Alcohol Blended Fuel

Blended fuel usually refers to a mixture composed of automotive gasoline and another liquid, other than a minimal amount of a product such as carburetor detergent or oxidation inhibitor that can be used as a fuel in a motor vehicle.

Alcohol refers to ethyl alcohol (ethanol, C_2H_5OH), which has a high octane number, RON being 110, and MON 90 and a good antiknock performance. If alcohol contains a certain amount of water, it is favorable to improve its antiknock performance; hence, the enhancement of the compression ratio of the engine occurs when the blended fuel is burned. Meanwhile, an alcohol blend requires no or reduced additive of antiknock substance, which may reduce air pollution caused by lead (Pb). But the effect on increasing of the octane number of blended fuel is not the same when gasoline is mixed with different kinds of alcohol.

The data (Table A-9) show that the change in octane number of blended fuel is in nonlinear correlation with the proportion of alcohol added. A 5 to 20% alcohol blend has a higher mixed octane number. This means that the effect on raising the octane number of blend fuel is more notable. In addition, the lower the octane number of base gasoline is, the more notable the effect on raising the octane number of blended fuel will be.

Table A-9 Octane number (motor method).

Ethanol, % v/v	Octane number
0	72.5
5	74.8
10	76.6
15	78.5
20	80.3
25	81.4
100	90.0

Selecting a 15 to 20% blend of alcohol has the advantage of the high antiknock performance of the alcohol. However, if low octane gasoline is used as the base for the blend, without adding any antiknock fluid, not only can the pollution be reduced but the cost of fuel is decreased, thus making the use of mixed fuel on gasoline engine more adaptable.

See also: Blended Fuels.

Alcohol-Diesel Emulsion

Because alcohols have limited solubility in diesel, a stable emulsion must be formed that will allow it to be injected before separation occurs. Numerous techniques have been evaluated to allow for the concurrent use of diesel and ethanol in compression ignition engines. Some of these techniques include alcohol fumigation, dual injection, alcohol-diesel fuel emulsions, and alcohol-diesel fuel blends. Among these approaches, only alcohol-diesel *emulsions* and *blends* are compatible with most commercial diesel engines. Since emulsions are difficult to achieve and tend to be unstable, blends—either as micro-emulsions or using co-solvents—are the most common approach as they are stable and can be used in engines with relatively no modifications.

Blends of ethanol with diesel fuel are often referred to as E-Diesel or eDiesel or oxygenated diesel – a term that is not particularly precise since diesel blends containing methyl ester (biodiesel) or any other additive that includes oxygen can be also described as oxygenated diesel. In e-diesel blends, standard diesel fuel (such as US No. 2) is typically blended with up to 15% v/v of ethanol using an additive package that helps maintain blend stability and other properties such as the cetane number and the lubricity. The additive package may comprise from 0.2% to 5.0% v/v of the blend.

The use of e-diesel can bring some reductions in diesel PM emissions, while contradictory reports exist on its effect on nitrogen oxides, carbon monoxide, and emissions of hydrocarbon derivatives. Perhaps the biggest advantage of e-diesel is its partially renewable character, especially if renewable ethanol is used as the blending stock.

Alcohol Fuels

Various alcohols ($C_nH_{2n+1}OH$) are used as fuel for internal combustion engines. The first four aliphatic alcohols (methanol, ethanol, propanol, and butanol) are of interest as fuels because they can be synthesized chemically or biologically, and they have characteristics which allow them to be used in internal combustion engines. When obtained from biological materials and/or biological processes, the alcohols are often referred to as bioalcohols (for example, bioethanol). However, there is no chemical difference between biologically produced and chemically produced alcohols.

Most methanol is produced from natural gas, although it can be produced from biomass using similar chemical processes. Ethanol is commonly produced from biological material through fermentation processes. Butanol has the advantage in combustion engines in that its energy density is closer to gasoline than the simpler alcohols (while still retaining over 25% higher octane rating). However, biobutanol is currently more difficult to produce than ethanol or methanol.

One advantage shared by the four major alcohol fuels is the high octane rating which tends to increase the fuel efficiency and largely offsets the lower energy density of vehicular alcohol fuels (as compared to gasoline and diesel fuels), thus resulting in comparable fuel economy in terms of distance per volume metrics, such as kilometers per liter, or miles per gallon.

See also: Alcohol-Blended Fuel.

Alcohol Fuels – Ethanol

Ethanol is the predominant fuel produced from crops that, because of favorable properties, has been used as fuel in the United States since at least 1908, along with methanol and gasoline (Table A-10).

Table A-10 Selected physical and chemical properties of methanol, ethanol, and gasoline.

Property	Methanol CH ₃ OH	Ethanol C ₂ H ₅ OH	Gasoline C4-C12
Molecular weight (g/mol)	32	46	~114
Specific gravity	0.789 (25°C, 77°F)	0.788 (25°C, 77°F)	0.739 (16°C, 60°F)
Vapor density rel. to air	1.10	1.59	3.0 (-40)
Liquid density (g/cm ³ at 25°C, 77°F)	0.79	0.79	3.0 to 4.0
Vapor pressure, 38°C (100°F)	4.6	2.5	8-10
Heat of evaporation (Btu/lb)	472	410	135
Heating value (kBtu gal ⁻¹)			
Lower (LHV)	58	74	111
Upper (UHV)	65	85	122
Viscosity (cp)	0.54	1.20	0.56
Flash point (°C, °F)	11 (52)	14 (57)	-36 (-33)
Flammability/explosion limits			
(%) Lower (LFL)	6.7	3.3	1.3
(%) Upper (UFL)	36	19	7.6

Although early efforts to sustain an ethanol program failed, oil supply disruptions in the Middle East and environmental concerns over the use of lead as a gasoline octane booster renewed interest in ethanol in the late 1970s. At present, extending the volume of conventional gasoline is a significant end use for ethanol, as is its use as an oxygenate. To succeed in these markets, the cost of ethanol must be close to the wholesale price of gasoline, currently made possible by the federal ethanol subsidy. However, in order for ethanol to compete on its own merits the cost of producing it must be reduced substantially.

The production of ethanol from corn is a mature technology that holds much potential. Substantial cost reductions may be possible, however, if cellulose-based feedstocks are used instead of corn. Producers are experimenting with units equipped to convert cellulose-based feedstocks, using sulfuric acid to break down cellulose and hemicellulose into fermentable sugar. Although the process is expensive at present, advances in biotechnology could decrease conversion costs substantially. The feed for all ethanol fermentations is sugar - traditionally a hexose (a six-carbon or "C6" sugar) such as those present naturally in sugar cane, sugar beet, and molasses. Sugar for fermentation can also be recovered from starch, which is actually a polymer of hexose sugars (*polysaccharide*).

Biomass, in the form of wood and agricultural residues such as wheat straw, is viewed as a low cost alternative feed to sugar and starch. It is also potentially available in far greater quantities than sugar and starch feeds. As such, it receives significant attention as a feed material for ethanol production. Like starch, wood and agricultural residues

contain polysaccharides. However, unlike starch, while the cellulose fraction of biomass is principally a polymer of easily fermented hexose (C6) sugars, the hemicellulose fraction is principally a polymer of pentose (C5) sugars; with quite different characteristics for recovery and fermentation, the cellulose and hemicellulose in biomass are bound together in a complex framework of crystalline organic material known as lignin.

These differences mean that recovery of these biomass sugars is more complex than recovery of sugars from a starch feedstock. Once recovered, fermentation is also more complex than a simple fermentation of hexose sugars. The current focus focuses on the issues of releasing the sugars (hydrolysis) and then fermenting as much of the C6 and C5 sugars as possible to produce ethanol.

There are several different methods of hydrolysis: (i) concentrated sulfuric acid, (ii) dilute sulfuric acid, (iii) nitric acid, and (iv) acid pretreatment followed by enzymatic hydrolysis.

Ethanol is produced from the fermentation of sugar by enzymes produced from specific varieties of yeast. The five major sugars are the five-carbon xylose and arabinose and the six-carbon glucose, galactose, and mannose. Traditional fermentation processes rely on yeasts that convert six-carbon sugars to ethanol. Glucose, the preferred form of sugar for fermentation, is contained in both carbohydrates and cellulose. Because carbohydrates are easier than cellulose to convert to glucose, the majority of ethanol currently produced in the United States is made from corn, which produces large quantities of carbohydrates. Also, the organisms and enzymes for carbohydrate conversion and glucose fermentation on a commercial scale are readily available.

The conversion of cellulosic biomass to ethanol parallels the corn conversion process. The cellulose must first be converted to sugars by hydrolysis and then fermented to produce ethanol. Cellulosic feedstocks (composed of cellulose and hemicellulose) are more difficult to convert to sugar than are carbohydrates. Two common methods for converting cellulose to sugar are dilute acid hydrolysis and concentrated acid hydrolysis, both of which use sulfuric acid.

Dilute acid hydrolysis occurs in two stages to take advantage of the differences between hemicellulose and cellulose. The first stage is performed at low temperature to maximize the yield from the hemicellulose, and the second, higher temperature stage is optimized for hydrolysis of the cellulose portion of the feedstock. Concentrated acid hydrolysis uses a dilute acid pretreatment to separate the hemicellulose and cellulose. The biomass is then dried before the addition of the concentrated sulfuric acid. Water is added to dilute the acid and then heated to release the sugars, producing a gel that can be separated from residual solids. Column chromatographic is used to separate the acid from the sugars.

Both the dilute and concentrated acid processes have several drawbacks. Dilute acid hydrolysis of cellulose tends to yield a large amount of by-products. Concentrated acid hydrolysis forms fewer by-products, but for economic reasons, the acid must be recycled. The separation and concentration of the sulfuric acid add more complexity to the process. The concentrated and dilute sulfuric acid processes are performed at high temperatures (100 and 220°C, 212 and 430°F) which can degrade the sugars, reducing the carbon source and ultimately lowering the ethanol yield. Thus, the concentrated acid process has a smaller potential for cost reductions from process improvements such as acid recovery and sugar yield for the concentrated acid process could provide higher efficiency for both technologies.

Another approach involves countercurrent hydrolysis, a two-stage process. In the first stage, cellulose feedstock is introduced to a horizontal co-current reactor with a conveyor. Steam is added to raise the temperature to 180°C (355°F; no acid is added at this point). After a residence time of approximately 8 minutes, during which some 60% of the hemicellulose is hydrolyzed, the feed exits the reactor. It then enters the second stage through a vertical reactor operated at 225°C (435°F). Very dilute sulfuric acid is added to the feed at this stage, where virtually all of the remaining hemicellulose and, depending on the residence time, anywhere from 60% w/w to all of the cellulose is hydrolyzed. The countercurrent hydrolysis process offers higher efficiency (and, therefore, cost reductions) than the dilute sulfuric acid process. This process may allow an increase in glucose yields to 84% w/w, an increase in fermentation temperature to 55°C (131°F), and an increase in fermentation yield of ethanol to 95% w/w.

The greatest potential for ethanol production from biomass, however, lies in enzymatic hydrolysis of cellulose. The enzyme cellulase, now used in the textile industry to stone wash denim and in detergents, simply replaces the sulfuric acid in the hydrolysis step. The cellulase can be used at lower temperatures, 30 to 50°C (86 to 122°F), which reduces the degradation of the sugar. In addition, process improvements now allow simultaneous saccharification and fermentation (SSF). In the saccharification and fermentation process, cellulase and fermenting yeast are combined, so that as sugars are produced, the fermentative organisms convert them to ethanol in the same step. Once

the hydrolysis of the cellulose is achieved, the resulting sugars must be fermented to produce ethanol. In addition to glucose, hydrolysis produces other six-carbon sugars from cellulose and five-carbon sugars from hemicellulose that are not readily fermented to ethanol by naturally occurring organisms. They can be converted to ethanol by genetically engineered yeasts that are currently available, but the ethanol yields are not sufficient to make the process economically attractive. It also remains to be seen whether the yeasts can be made hardy enough for production of ethanol on a commercial scale.

A large variety of feedstocks is currently available for producing ethanol from cellulosic biomass. The materials being considered can be categorized as agricultural waste, forest residue, and energy crops. Agricultural waste available for ethanol conversion includes crop residues such as wheat straw, corn stover (leaves, stalks, and cobs), rice straw, and bagasse (sugar cane waste). Forestry waste includes underutilized wood and logging residues; rough, rotten, and salvable dead wood; and excess saplings and small trees. Energy crops, developed and grown specifically for fuel, include fast-growing trees, shrubs, and grasses such as hybrid poplars, willows, and switchgrass.

Briefly, corn stover is the leaves and stalks of field crops, such as corn (maize), sorghum, or soybean that are commonly left in a field after harvesting the grain. Corn stover is similar to straw, which is the residue left after any cereal grain or grass has been harvested at maturity for its seed and can be directly grazed by cattle or dried for use as fodder; stover has attracted some attention as a potential fuel source, and as a biomass feedstock for fermentation or as a feedstock for ethanol production from cellulose.

Although the choice of feedstock for ethanol conversion is largely a cost issue, feedstock selection has also focused on environmental issues. Materials normally targeted for disposal include forest thinnings collected as part of an effort to improve forest health, and certain agricultural residues, such as rice straw. Also, forest residues represent an opportunity to decrease the fire hazard associated with the dead wood present in many forests. Small quantities of forest thinnings can be collected at relatively low cost, but collection costs rise rapidly as quantities increase.

Agricultural residues, in particular corn stover, represent a tremendous resource base for biomass ethanol production. Agricultural residues, in the long term, would be the sources of biomass that could support substantial growth of the ethanol industry. At conversion yields of around 60 to 100 gal per dry ton, the available corn stover inventory would be sufficient to support 7 to 12 billion (7 to 12×10^9) gal of ethanol production per year.

Dedicated energy crops such as switchgrass, hybrid willow, and hybrid poplar are another long-term feedstock option. Switchgrass is grown on a 10-year crop rotation basis, and harvest can begin in year 1 in some locations and year 2 in others. Willows require a 22-year rotation, with the first harvest in year 4 and subsequent harvests every 3 years thereafter. Hybrid poplar requires 6 years to reach harvest age in the Pacific Northwest, 8 years in the Southeast, Southern Plains, and South Central regions, and 10 years in the Corn Belt, Lake States, Northeast and Northern Plains regions.

The use of cellulosic biomass in the production of ethanol also has environmental benefits. Converting cellulose to ethanol increases the net energy balance of ethanol compared to converting corn to ethanol. The net energy balance is calculated by subtracting the energy required to produce a gallon of ethanol from the energy contained in a gallon of ethanol (approximately 76,000 Btu). Corn-based ethanol has a net energy balance of 20,000 to 25,000 Btu per gallon, whereas cellulosic ethanol has a net energy balance of more than 60,000 Btu per gallon. In addition, cellulosic ethanol use can reduce greenhouse gas emissions. Cellulosic ethanol can produce an 8 to 10% reduction in greenhouse gas emissions when used in E10 and a 68 to 91% reduction when used in E85.

Alcohol Fuels - Methanol

Alcohols are organic compounds that contain at least one hydroxyl functional group ($-\text{OH}$) bound to a saturate carbon atom. The term alcohol originally referred to the primary alcohol ethanol (ethyl alcohol, $\text{CH}_3\text{CH}_2\text{OH}$ or $\text{C}_2\text{H}_5\text{OH}$), which is used as a drug or as a relaxant-intoxicant in the form of alcoholic beverages. An important class of alcohols, of which methanol (methyl alcohol, CH_3OH) and ethanol are the simplest members, includes all compounds for which the general formula is $\text{C}_n\text{H}_{2n+1}\text{OH}$. Simple mono-alcohols (one hydroxyl group per molecule) include the primary alcohol derivatives (RCH_2OH), the secondary alcohol derivatives (R_2CHOH), and the tertiary alcohol derivatives (R_3COH) alcohols.

Methanol is a colorless, odorless, and nearly tasteless alcohol and is also produced from crops and is also used as a fuel. Methanol, like ethanol, burns more completely but releases as much or more carbon dioxide than its gasoline counterpart. The balance is often seen as the various bi-processes that draw carbon dioxide from the atmosphere so there is no net modern release, as there is for fossil fuels.

Methanol and other chemicals were routinely extracted from wood in the 19th Century and in the early 20th Century. However, the original route for methanol recovery from biomass was quite different to current routes. Methanol was originally recovered from wood as a by-product of charcoal manufacture, and was often called *wood alcohol*. Pyrolysis (heating wood in the absence of air) to above 270°C in a retort causes thermal cracking or break-down of the wood and allows much of the wood to be recovered as charcoal. The watery condensate leaving the retort contained methanol, among other compounds. In 1923, commercial production of methanol from synthesis gas by a catalytic process was commenced. Now, almost all of the methanol used worldwide comes from the processing of natural gas.

In general, methanol production from natural gas feed consists of three steps: (i) generation of synthesis gas – in the case of natural gas feed, synthesis gas production consists of converting methane (CH_4) into carbon monoxide (CO) and hydrogen (H_2) via steam reforming, (ii) synthesis gas upgrading - primarily removal of carbon dioxide, plus any contaminants such as sulfur, and (iii) methanol synthesis and purification - reacting the carbon monoxide, hydrogen, and steam over a catalyst in the presence of a small amount of carbon dioxide and at elevated temperature and pressure. The methanol synthesis is an equilibrium reaction, and excess reactants must be recycled to optimize yields.

Modern methods proposed for the production of methanol from biomass involve the conversion of the biomass to a suitable synthesis gas, after which processing steps are very similar to those developed for methanol from natural gas. However, the gasification techniques proposed are still at a relatively early stage of development using biomass feed and the methods are based on similar techniques used widely already with natural gas as feed.

Before biomass can be gasified, it must be pre-treated to meet the processing constraints of the gasifier. This typically involves size reduction, and drying to keep moisture contents below specific levels. Thereafter, biomass gasification involves heating biomass in the presence of low levels of oxygen (i.e., less than required for complete combustion to carbon dioxide and water). Above certain temperatures, the biomass will break down into a gas stream and a solid residue. The composition of the gas stream is influenced by the operating conditions for the gasifier, with some gasification processes more suited than others to producing a gas for methanol production. In particular, simple gasification with air creates a synthesis gas stream that is diluted with large quantities of nitrogen. This nitrogen is detrimental to subsequent processing to methanol, and so techniques using indirect gasification or an oxygen feed are preferred. For large-scale gasification, pressurized systems are considered to be more economic than atmospheric systems.

Once the economic optimum synthesis gas is available, the methanol synthesis takes place. This typically uses a copper-zinc catalyst at temperatures of 200 to 280°C and pressures of 50 to 100 atmospheres. The crude methanol from the synthesis loop contains water produced during synthesis as well as other minor by-products. Purification is achieved in multistage distillation, with the complexity of distillation dictated by the final methanol purity required.

Alcohol Fuels – Propanol and Butanol

Propanol and butanol are considerably less toxic and less volatile than methanol. In particular, butanol has a high flashpoint (35°C; 95°F), which is a benefit for fire safety, but may be a difficulty for starting engines in cold weather.

The fermentation processes to produce propanol and butanol from cellulose are fairly tricky to execute, and the *Clostridium acetobutylicum* currently used to perform these conversions produces an extremely unpleasant smell, and this must be taken into consideration when designing and locating a fermentation plant. This organism also dies when the butanol content of whatever it is fermenting rises to 7%. For comparison, yeast dies when the ethanol content of its feedstock reaches 14%. Specialized strains can tolerate even greater ethanol concentrations - so-called turbo yeast can withstand up to 16% ethanol. However, if ordinary *Saccharomyces* yeast can be modified to improve its ethanol resistance, scientists may yet one day produce a strain of the Weizmann organism with a butanol

resistance higher than the natural boundary of 7%. This would be useful because butanol has a higher energy density than ethanol, and because waste fiber left over from sugar crops used to make ethanol could be made into butanol, raising the alcohol yield of fuel crops without there being a need for more crops to be planted.

Alcohols

Alcohol is the family name of a group of organic chemical compounds composed of carbon, hydrogen, and oxygen and has fuel properties (Table A-11). The molecules in the series vary in chain length and are composed of a hydrocarbon plus a hydroxyl group. Alcohols are oxygenated fuels insofar as the alcohol molecule has one or more oxygen, which decreases to the combustion heat. Practically, any of the organic molecules of the alcohol family can be used as a fuel. The alcohols can be used for motor fuels are methanol (CH_3OH), ethanol ($\text{C}_2\text{H}_5\text{OH}$), propanol ($\text{C}_3\text{H}_7\text{OH}$), and butanol ($\text{C}_4\text{H}_9\text{OH}$). However, only methanol and ethanol fuels are technically and economically suitable for internal combustion engines.

Table A-11 Fuel properties of methanol and ethanol compared to the properties of iso-octane.

Item	Iso-octane	Methanol	Ethanol
Formula	C_8H_{18}	CH_3OH	$\text{C}_2\text{H}_5\text{OH}$
Molecular weight	114.224	32.042	46.07
Carbon, % w/w	84.0	37.5	52.17
Hydrogen, % w/w	16.0	12.5	13.4
Oxygen, , % w/w	0	50.0	34.78
Boiling point @ 1 atmosphere °C	99.239	64.5	78.40
Freezing point @ 1 atmosphere °C	-107.378	-97.778	-80.00
Density @ 15.5 °C lb/gal	5.795	6.637	6.63
Viscosity @ 20°C, Centipoise	0.503	0.596	1.20
Specific heat @ 25°C/1 atm. Btu/lb	0.5	0.6	0.6
Heat of vaporization, @ boiling point/1 atm. Btu/lb	116.69	473.0	361.0
Heat of vaporization, @ 25°C/1 atm. Btu/lb	132.0	503.3	
Heat of combustion @ 25°C, Btu/lb			
Higher heating value	20555	9776	12780
Lower heating value	19065	8593	11550
Research octane number	100	106	105
Flash point, °C	-42.778	11.112	12.778
Auto-ignition temperature, °C	257.23	463.889	422.778
Flammability limits			
Lower	1.4	6.7	4.3
Higher	7.6	36.0	19.0

The alcohols are named accordingly to the basic molecules of hydrocarbon which derives from them: methanol (CH_3OH); ethanol ($\text{C}_2\text{H}_5\text{OH}$); propanol ($\text{C}_3\text{H}_7\text{OH}$); and butanol ($\text{C}_4\text{H}_9\text{OH}$), although menthol and ethanol are the most frequently used as fuel because of their distinguishing properties. Theoretically, any of the organic molecules of the alcohol family can be used as a fuel. The list is somehow more extensive; however, only two of the alcohols are technically and economically suitable as fuels for internal combustion engines. These alcohols are those of the simplest molecular structure, i.e., methanol (CH_3OH) and ethanol ($\text{C}_2\text{H}_5\text{OH}$) (Table A-11).

Methanol is produced by a variety of process, the most common are as follows: distillation of wood; distillation of coal; natural gas; and crude oil gas. Ethanol is produced mainly from biomass transformation, or bioconversion. It can also be produced by synthesis from crude oil or mineral coal.

In those countries with large territorial areas, ethanol has been the renewable fuel choice to replace gasoline. The reason is the fact that alcohol is a renewable source of energy. Currently, ethanol is produced from sugar beets and from molasses - a typical yield is 15 to 20 gal of ethanol per ton of sugar cane. Other crops can be used for the production of ethanol. Corn, for example, can yield approximately 75 gal liters of alcohol.

Ethanol (ethyl alcohol, $\text{CH}_3\text{CH}_2\text{OH}$), also referred to as bioethanol, is a clear, colorless liquid with a characteristic, agreeable odor. Currently, the production of ethanol by fermentation of corn-derived carbohydrates is the main technology used to produce liquid fuels from biomass resources.

Ethanol can be blended with gasoline to create E85, a blend of 85% ethanol and 15% gasoline. Fuel with higher concentrations of ethanol (E95) and pure bioethanol (E100) has been used successfully in Brazil. More widespread practice has been to add up to 20% to gasoline (E20, also called gasohol) to avoid engine changes. E100-fueled and M100-fueled vehicles have difficulty starting in cold weather, but this is not a problem for E85 and M85 vehicles because of the presence of gasoline.

Ethanol has a higher octane number (108), broader flammability limit, higher flame speed, and a higher heat of vaporization than gasoline. These properties allow for a higher compression ratio, shorter burn time, and leaner burn engine, which lead to theoretical efficiency advantages over gasoline in an internal combustion engine. On the other hand, the disadvantages of ethanol include its lower energy density than gasoline, corrosiveness, low flame luminosity, lower vapor pressure, miscibility with water, and toxicity to ecosystems.

The alcohols mix in all proportions with water due to the polar nature of the hydroxyl (OH) group. Low volatility is indicated by high boiling point and high flash point. Alcohols burn with no luminous flame, and methanol produces almost no soot, but the tendency to produce soot increases with molecular weight.

See also: Alcohols – Production, Ethanol, Methanol.

Alcohols – Combustion

There are some important differences in the combustion characteristics of alcohols and hydrocarbon derivatives. Alcohols have higher flame speeds and extended flammability limits. Also, alcohols produce a great number of product moles per mole of fuel burnt; therefore, higher pressure is achieved.

The alcohols mix in all proportions with water due to the polar nature of OH group. Low volatility is indicated by high boiling point and high flash point. Alcohols burn with no luminous flame and produce almost no soot, especially methanol. The tendency to soot formation increases with molecular weight.

Combustion of alcohol in presence of air can be initiated by an intensive source of localized energy, such as a flame or a spark, and also, the mixture can be ignited by application of energy by means of heat and pressure, such as happens in the compression stroke of a piston engine. The energy of the mixture reaches a level sufficient for ignition to take place after a brief period of delay called ignition delay, or induction time, between the sudden heating of the mixture and the onset of ignition (formation of a flame front which propagates at high speed throughout the whole mixture). The high latent heat of vaporization of alcohols cools the air entering the combustion chamber of the engine, thereby increasing the air density and mass flow. This leads to increased volumetric efficiency and reduced compression temperatures. Together with the low level of combustion temperature, these effects also improve the thermal efficiency by 10%.

Alcohols have higher flame speeds and extended flammability limits than hydrocarbons. Also, alcohols produce a great number of product moles per mole of fuel burnt; therefore, higher pressure is achieved. The higher flame speed, giving earlier energy release in the power stroke, results in a power increase of 11% at normal conditions and up to 20% at the higher levels of a compression ratio (14:1). The power continues to rise steadily as the mixture is enriched to an equivalence ratio of approximately 1 to 4. Because of the low proportion of carbon in alcohols, soot formation does not occur and therefore alcohols burn with low luminosity and therefore low radiation. In conjunction with lower flame temperature, approximately 10% less heat is lost to the engine coolant. The lower flame temperature of alcohols results in much lower NO_x (nitrogen oxides) emissions. The wider flammability limits of alcohols permit smooth engine operation even at very lean mixtures. But aldehyde emissions are noticeably higher. For ethanol, emissions are acetaldehydes, and for methanol, emissions are of formaldehydes. Increasing compression ratio from 9 to 14, aldehyde emissions can be reduced by 50%, to a level compared to that for gasoline. An addition of 10% water reduces aldehyde emissions by 40% and NO_x by 50%. Addition of 10% water in the alcohol can be tolerated without loss of thermal efficiency.

The oxygen content of alcohols depresses the heating value of the fuel in comparison with hydrocarbon fuels. The heat of combustion per unit volume of alcohol is approximately half that of isooctane. However, the stoichiometric fuel-air mass ratios are such big that the quantity of energy content based on unit mass of stoichiometric mixture becomes comparable with that of hydrocarbon derivatives.

Methanol is not miscible with hydrocarbon derivatives, and separation ensues readily in the presence of small quantities of water, particularly with reduction in temperature. Anhydrous ethanol, on the other hand, is completely miscible in all proportions with gasoline, although separation may be affected by water addition or by cooling. If water is already present, the water tolerance is higher for ethanol than for methanol, and can be improved by the addition of higher alcohols, such as butanol.

The high heat of vaporization and constant boiling point make cold starting difficult with neat alcohols. The problem is not as severe as in case of alcohols blended with gasoline. Ethanol has a constant boiling point of 80°C (176°F). Gasoline which has a high vapor pressure (therefore highly volatile) can be used for cold start.

See also: Alcohols, Butanol, Ethanol, Methanol, Propanol.

Alcohols – Corrosivity

Dry methanol is very corrosive to some aluminum alloys, but additional water at 1% almost completely inhibits corrosion. It must be noted that methanol with additional water at more than 2% becomes corrosive again. The same happens with less than 1% water. Nitride and neoprene rubbers, generally satisfactory as elastomers in contact with methanol and polyacetal plastics, are very resistant. Silicon rubber as well as vinyl can be used for gasket material. Ethanol always contains acetic acid and is particularly corrosive to aluminum alloys. Also, certain alloys containing lead are attacked with a general result of the lead being leached out, leaving a porous surface. The same phenomenon exists with alloys of zinc, such as ZAMAC (zinc plus aluminum), and the zinc is leached out as a white zinc oxide, which clogs the small orifices and jets.

Carburetors are normally made of ZAMAC alloy. Experience has shown that if the carburetor is protected with a coat of nickel, the corrosion problem is overcome. The process recommended is electrolysis nickel plating. In this process, the carburetor parts are immersed in a bath of hot nickel, which, due to the low viscosity, covers evenly all the surfaces without clogging the orifices. The floats on the carburetor float-bowl are generally made of porous plastics which are attacked by the ethanol, and the end result is swelling and cracking. It is found that nylon floats are more durable. A float can be made with thin sheet of brass (0.005 in) or 0.125 mm thickness, molded and welded with pure tin (Sn).

Alloys of tin and lead (Sn+ Pb) shall be avoided as welding material. All bronze parts shall be brass or stainless steel. Steel fuel lines shall be replaced by nylon tube (Nylon 11). Fuel filters used for gasoline are not recommended for the many alcohols. The internal element collapses after the glue that bonds it together is softened by the alcohol. Special filters are necessary. Also, due to the higher flows, filters have to be bigger. The filter body must be made of nylon or Teflon.

Alcohols – From Waste

Alcohols can be made from organic materials by fermentation, and there is the potential for the production of alcohols from organic waste. Historically, the production of methanol, ethanol, and higher molecular alcohols from syngas has been known since the beginning of the 20th century. There are several processes that can be used to make mixed alcohols from synthesis gas including iso-synthesis, variants of Fischer-Tropsch synthesis, oxo-synthesis involving the hydroformylation of olefins, and homologation of methanol and lower molecular weight alcohols to make higher alcohols. In the context of the Fischer-Tropsch process, depending on the process and its operating conditions, the most abundant products are usually methanol and carbon dioxide, but methanol can be recycled to produce higher molecular weight alcohols.

With the development of various gas-to-liquid processes, it was recognized that higher alcohols were by-products of these processes when catalysts or conditions were not optimized. Modified Fischer-Tropsch (or methanol synthesis) catalysts can be promoted with alkali metals to shift the products toward higher alcohols. Synthesis of higher molecular weight alcohols is optimal at higher temperatures and lower space velocities compared to methanol synthesis and with a ration of hydrogen/carbon monoxide ratio of approximately 1 rather than 2 or greater.

In the process, the feedstock enters the process and is converted to synthesis gas with the desired carbon monoxide/hydrogen ratio, which is then reacted, in the presence of a catalyst, into methanol (CH₃OH), ethanol (CH₃CH₂OH), and higher molecular weight alcohols.

Thus,

Stoichiometry suggests that the carbon monoxide/hydrogen ratio is optimum at 2, but the simultaneous presence of water-gas shift leads to an optimum ratio closer to 1.

As in other synthesis gas conversion processes, the synthesis of higher molecular weight alcohols generates significant heat and an important aspect is choice of the proper reactor to maintain even temperature control which then maintains catalyst activity and selectivity. In fact, the synthesis of higher molecular weight alcohols is carried out in reactors similar to those used in methanol and Fischer-Tropsch synthesis. These include shell and tube reactors with shell-side cooling, trickle-bed, and slurry bed reactors.

Catalysts for the synthesis of higher molecular weight alcohols generally fall mainly into four groups: (1) modified high pressure methanol synthesis catalysts, such as alkali-doped ZnO/Cr₂O₃, (2) modified low pressure methanol catalysts, such as alkali-doped Cu/ZnO and Cu/ZnO/Al₂O₃, (3) modified Fischer-Tropsch catalysts, such as alkali-doped CuO/CoO/Al₂O₃, and (4) alkali-doped sulfides, such as mainly molybdenum sulfide (MoS₂).

The catalytic synthesis process makes several different alcohols depending, in part, on residence time in the reactor and the nature of the catalyst. The alcohols can be separated by distillation and dried to remove water.

A further aspect of the waste-to-alcohols concept is the use of a plasma field (<http://www.fuelfrontiers.com/technology.htm>) in which temperatures are reputed (but not yet proved) to reach 30,000°C (54,000°F). The feedstock can be materials such as waste coal, used tires, wood wastes, raw sewage, municipal solid wastes, biomass, discarded roofing shingles, coal waste (*culm*), and discarded corn stalks. The plasma field breaks down the feedstock into their core elements in a clean and efficient manner.

See also: Alcohols.

Alcohols – Production

Alcohols can be produced from a variety of feedstocks. For example, ethanol is produced from organic feedstocks, such as biomass, by a fermentation process. However, recent efforts have focused on the production of ethanol

from waste materials using a gasification process. The overall process consists of a thermochemical conversion of synthesis gas which is then converted to higher molecular weight alcohols by a catalytic process, after which high purity ethanol is separated by distillation. The process is similar to the methanol and gas-to-liquid process. The key differentiating factors are the catalysts and their operating parameters.

Alcohols can be made directly from organic feedstocks (such as sugars and sugar derivatives) by fermentation or indirectly by the production of synthesis gas, and there is the potential for the production of alcohols from organic waste.

synthesis gas methanol ethanol

Historically, the production of methanol, ethanol, and higher molecular alcohols from synthesis gas has been known since the beginning of the 20th century. There are several processes that can be used to make mixed alcohols from synthesis gas including iso-synthesis, variants of Fischer-Tropsch synthesis, oxo-synthesis involving the hydroformylation of olefins, and homologation of methanol and lower molecular weight alcohols to make higher alcohols. In the context of the Fischer-Tropsch process, depending on the process and its operating conditions, the most abundant products are usually methanol and carbon dioxide, but methanol can be recycled to produce higher molecular weight alcohols.

With the development of various gas-to-liquid processes, it was recognized that higher alcohols were by-products of these processes when catalysts or conditions were not optimized. Modified Fischer-Tropsch (or methanol synthesis) catalysts can be promoted with alkali metals to shift the products toward higher alcohols. Synthesis of higher molecular weight alcohols is optimal at higher temperatures and lower space velocities compared to methanol synthesis and with a hydrogen/carbon monoxide ratio of approximately 1 rather than 2 or greater.

In the process, the feedstock enters the process and is converted to synthesis gas with the desired carbon monoxide/hydrogen ratio, which is then reacted, in the presence of a catalyst, into methanol (CH₃OH), ethanol (CH₃CH₂OH), and higher molecular weight alcohols.

Thus,

Stoichiometry suggests that the carbon monoxide/hydrogen ratio is optimum at 2, but the simultaneous presence of water-gas shift leads to an optimum ratio closer to 1.

As in other synthesis gas conversion processes, the synthesis of higher molecular weight alcohols generates significant heat and an important aspect is choice of the proper reactor to maintain even temperature control which then maintains catalyst activity and selectivity. In fact, the synthesis of higher molecular weight alcohols is carried out in reactors similar to those used in methanol and Fischer-Tropsch synthesis. These include shell and tube reactors with shell-side cooling, trickle-bed, and slurry bed reactors.

Catalysts for the synthesis of higher molecular weight alcohols generally fall mainly into four groups: (i) modified high pressure methanol synthesis catalysts, such as alkali-doped ZnO/Cr₂O₃, (ii) modified low pressure methanol catalysts, such as alkali-doped Cu/ZnO and Cu/ZnO/Al₂O₃, (iii) modified Fischer-Tropsch catalysts, such as alkali-doped CuO/CoO/Al₂O₃, and (iv) alkali-doped sulfides, such as mainly molybdenum sulfide (MoS₂).

The catalytic synthesis process makes several different alcohols depending, in part, on residence time in the reactor and the nature of the catalyst. The alcohols can be separated by distillation and dried to remove water.

A further aspect of the waste-to-alcohols concept is the use of a plasma field in which temperatures are reputed (but not yet proved) to reach 30,000°C (54,000°F). The feedstock can be materials such as waste coal, used tires, wood wastes, raw sewage, municipal solid wastes, biomass, discarded roofing shingles, coal waste (culm), and discarded corn stalks. The plasma field breaks down the feedstock into their core elements in a clean and efficient manner.

Most efforts for alcohol production have centered on bacteria, enzyme, and acid/solvent hydrolysis fermentation-based ethanol production. However, the action of bacteria and enzymes is often very dependent on the feedstock. In addition, these processes generate a small quantity of ethanol over a period of days and the dilute aqueous ethanol product must be distilled to recover the ethanol. In the gasification-synthesis process, various carbonaceous feedstocks can be used, with appropriate modifications in the synthesis gas production step.

A new system for converting trash into ethanol and methanol could help reduce the amount of waste piling up in landfills while displacing a large fraction of the fossil fuels used to power vehicles in the United States. The technology developed does not incinerate refuse, so it does not produce the pollutants that have historically plagued efforts to convert waste into energy. Instead, the technology vaporizes organic materials to produce synthesis gas that can be used to synthesize a wide variety of fuels and chemicals. In addition to processing municipal waste, the technology can be used to create ethanol out of agricultural biomass waste, providing a potentially less expensive way to make ethanol than current corn-based plants.

The new system makes synthesis gas in two stages. In the first stage, waste is heated in a 1,200°C (2,190°F) chamber into which a controlled amount of oxygen is added to partially oxidize carbon and free hydrogen. Not all of the organic material is converted, and some forms char which is then gasified when researchers pass it through arcs of plasma. The remaining inorganic materials, including toxic substances, are oxidized and incorporated into a pool of molten glass which hardens into a material that can be used for building roads or discarded as a safe material in landfills. The second stage is a catalyst-based process for converting synthesis gas into equal ethanol and methanol.

Ethanol from cellulosic biomass materials (such as agricultural residues, trees, and grasses) is made by first using pretreatment and hydrolysis processes to extract sugars, followed by fermentation of the sugars. Although producing ethanol from cellulosic biomass is currently more costly than producing ethanol from starch crops, several countries (including the United States) have launched biofuel initiatives with the objective of the economic production of ethanol from bio-sources. In the process, the carbohydrate from the biomass is converted to a sugar derivative; this is converted to ethanol in a fermentation process that is similar to the process for brewing beer; typical feedstocks for the process are sugar beets and from molasses.

Ethanol can also be produced by synthesis from the chemical compound ethylene, which is derived from crude oil or natural gas, or by the fermentation of carbohydrates.

Methanol (methyl alcohol, wood alcohol, CH_3OH) is mainly manufactured from natural gas, but biomass can also be gasified to methanol. Methanol can be made with any renewable resource containing carbon such as seaweed, waste wood, and garbage. Methanol is stored and handled like gasoline because it is produced as a liquid. Methanol is currently made from natural gas, but it can also be made from a wide range of renewable biomass sources, such as wood or waste paper.

Methanol can be used as one possible replacement for conventional motor fuels and, like ethyl alcohol, has a high octane rating; hence an Otto engine is preferable. If an ignition booster is used, methanol can be used in a diesel engine.

Methanol also offers important emissions benefits compared with gasoline. It can reduce hydrocarbon emissions by 30 to 40% with M85 and up to 80% with M100 fuels. Methanol costs less than gasoline, but has lower energy content. Taking this into account, costs for methanol in a conventional vehicle are slightly higher than those for gasoline.

However, methanol is not miscible with hydrocarbon derivatives and separation ensues readily in the presence of small quantities of water, particularly with reduction in temperature. Anhydrous ethanol, on the other hand, is completely miscible in all proportions with gasoline, although separation may be effected by water addition or by

cooling. If water is already present, the water tolerance is higher for ethanol than for methanol, and can be improved by the addition of higher alcohols, such as butanol. Also, benzene or Acetone can be used.

Algaculture

Algaculture is a form of aquaculture involving the farming of species of algae. The majority of algae that are intentionally cultivated fall into the category of microalgae (also referred to as phytoplankton, microphytes, or planktonic algae).

Macroalgae (seaweed) also have many commercial and industrial uses, but due to their size and the specific requirements of the environment in which they need to grow, they do not lend themselves as readily to cultivation. However, as the algae grow and multiply, the culture becomes so dense that it blocks light from reaching deeper into the water. Direct sunlight is too strong for most algae, which need only approximately 10% of the amount of light they receive from direct sunlight.

Algae can be cultured in open-ponds which are vulnerable to contamination by other microorganisms, such as other algal species or bacteria. Thus cultivators usually choose closed systems for monocultures. Open systems also do not offer control over temperature and lighting. The growing season is largely dependent on location and, aside from tropical areas, is limited to the warmer months.

Open pond systems are cheaper to construct, at the minimum requiring only a trench or pond. Large ponds have the largest production capacities relative to other systems of comparable cost. Open pond cultivation can exploit unusual conditions that suit only specific algae and can also work if there is a system of culling the desired algae and inoculating new ponds with a high starting concentration of the desired algae.

Enclosing a pond with a transparent or translucent barrier effectively turns it into a greenhouse. This allows more species to be grown; it allows the species that are being grown to stay dominant; and it extends the growing season – and if heated, the pond can produce year round.

Algae can also be cultured in a photobioreactor (PBR) which is a bioreactor that incorporates a light source. However, because photobioreactor systems are closed, the cultivator must provide all nutrients, including carbon dioxide. A photobioreactor can operate in batch mode, which involves restocking the reactor after each harvest, but it is also possible to grow and harvest continuously. Continuous operation requires precise control of all elements to prevent immediate collapse. The grower provides sterilized water, nutrients, air, and carbon dioxide at the correct rates. This allows the reactor to operate for long periods.

Algae

Algae are a large and diverse group of simple, typically autotrophic organisms, ranging from unicellular to multicellular forms. The largest and most complex marine forms are called seaweeds, which are photosynthetic but lack the many distinct organs found in land plants. Microalgae are organisms that are less than 0.4 mm in diameter and include the diatoms and cyanobacteria and are capable of photosynthesis. Macroalgae are organisms such as seaweed.

Algae are not highly differentiated in the way that plants are, and they lack true roots, stems and leaves, and a vascular system to circulate water and nutrients throughout their bodies. They can exist as single, microscopic cells; they can be macroscopic and multicellular; live in colonies; or take on a leafy appearance as in the case of seaweeds.

The general term algae includes prokaryotic organisms cyanobacteria, also known as blue-green algae, as well as eukaryotic organisms (all other algal species). Algae lack the various structures that characterize land plants, such as leaves, roots, and other organs that are found in vascular plants. Many algae are photoautotrophic, although some groups contain members that are mixotrophic, deriving energy both from photosynthesis and uptake of organic

carbon. Some unicellular species rely entirely on external energy sources and have limited or no photosynthetic apparatus.

The majority of algae live in aquatic habitats and these organisms can thrive in freshwater lakes or in saltwater oceans. They can also endure a range of temperatures, oxygen or carbon dioxide concentrations, acidity, and turbidity. An important contribution of algae to the environment and well-being is the generation of oxygen through photosynthesis.

Algal biofuels are a promising replacement for fossil fuels. All algae have the ability to produce energy-rich oils, and several microalgal species naturally accumulate high levels of oil in their dry mass. Moreover, algae are found in diverse habitats and can reproduce quickly and also efficiently use carbon dioxide. Algae help to keep atmospheric carbon dioxide levels stable by storing carbon dioxide in organic materials that include crude oil and inorganic carbonate rocks. Green algae, diatoms, and cyanobacteria are just some of the microalgal species that are considered good candidates for the production of biofuel.

Algae Fuels

Algae fuel is a biofuel that is derived from algae, which are photosynthetic, eukaryotic, plant-like organisms that use chlorophyll in capturing light energy, but lack characteristic plant structures such as leaves, roots, flowers, vascular tissue, and seeds. The production of algae to harvest oil for biofuels has not yet been undertaken on a commercial scale. But algae potentially can be grown commercially in environments such as algae ponds at wastewater treatment plants and the oil extracted from the algae and processed into biofuels. During photosynthesis, algae and other photosynthetic organisms capture carbon dioxide.

The benefits of algal biofuel are that it can be produced industrially, thereby obviating the use of arable land and food crops (such as soy, palm, and canola), and that it has a high yield of oil when compared to other sources of biofuel. Thus, algaculture, unlike food crop-based biofuels, does not entail a decrease in food production, since it requires neither farmland nor fresh water.

Algae can produce up to 60% of their biomass in the form of oil. Because the cells grow in aqueous suspension where they have more efficient access to water, carbon dioxide, and dissolved nutrients, microalgae are capable of producing large amounts of biomass and usable oil in either high rate algal ponds or photobioreactors. This oil can then be turned into biodiesel. In fact, seaweeds, which are macroscopic, multicellular marine algae, may offer a particular useful source of biofuels, since they lack lignin and likewise do not require land, fresh water, or fertilizer. One complication is that approximately one-third of the sugars in seaweed take the form of alginate and microbes have not been able to convert it into ethanol.

In the process of oil production, the algae is harvested from the growing process as algae paste after which water is removed by heat drying or de-watering presses. Centrifuges are also another way in which the algae past can be de-watered. The finished product is algae oil in a form that is then suitable for use in the transesterification process to make biodiesel fuel.

The production of biofuel from algae does not reduce atmospheric carbon dioxide (CO_2), because any carbon dioxide taken out of the atmosphere by the algae is returned when the biofuels are burned. They do however eliminate the introduction of new carbon dioxide by displacing fossil hydrocarbon fuels. Also, algal fuels do not affect fresh water resources and they can be produced using ocean and wastewater. Algal fuels are also biodegradable and relatively harmless to the environment if spilled.

Open-pond systems for the most part have been given up for the cultivation of algae with high-oil content. Open systems using a monoculture are also vulnerable to viral infection. The energy that a high-oil strain invests into the production of oil is energy that is not invested into the production of proteins or carbohydrates, usually resulting in the species being less hardy, or having a slower growth rate. Algal species with lower oil content, not having to divert their energies away from growth, have an easier time in the harsher conditions of an open system.

The preference toward microalgae is due largely to its less complex structure, fast growth rate, and high oil content (for some species). Some commercial interests into large scale algal-cultivation systems are looking to tie in to existing infrastructures, such as coal power plants or sewage treatment facilities. This approach not only provides the raw

materials for the system, such as carbon dioxide and nutrients; it also changes those wastes into resources. However, there is interest in using seaweed for biofuels, probably due to the high availability of this resource.

Algae fuel is also very appealing in terms of its emissions as well. The combustion of algae fuel produces less carbon monoxide, unburned hydrocarbons, and harmful pollutants compared to crude oil-derived diesel fuel as well as emits no sulfur oxides. Replacing fossil fuels with algae could substantially reduce carbon dioxide emissions.

In addition, microalgae has a strong impact on wastewater, and systems for producing microalgae have the ability of being able to use saline waste, as well as carbon dioxide streams, as an energy source. This is because the algae from microalgae bioreactors is capable of capturing organic compounds and heavy metal contaminants in wastewater. As a result, the production of algae has the side effect of being able to recycle formerly unusable water. In fact, not only does this process clean waste water, but it also recovers phosphorus from the waste water. Phosphorus is a highly limited resource, so much so that the last reserves of phosphorus are estimated to have already been depleted.

Biogasoline is gasoline produced from biomass such as algae. Like traditionally produced gasoline, the constituents contain between 6 carbon atoms (hexane, C_6H_{14}) and 12 (dodecane, $C_{12}H_{26}$) carbon atoms per molecule and can be used in internal-combustion engines. Biogasoline is chemically different from biobutanol and bioethanol, as these are alcohols, not hydrocarbons.

Algae Fuels – Extraction

Algae fuels can be recovered by three processes: (i) physical extraction or (ii) chemical extraction, and (iii) enzymatic extraction.

In the first step of physical extraction, the oil must be separated from the rest of the algae. The simplest method is mechanical crushing. When algae are dried it retains its oil content, which can then be recovered using an oil press. Many commercial manufacturers of vegetable oil use a combination of mechanical pressing and chemical solvents in extracting oil. Since different strains of algae vary widely in their physical attributes, various press configurations (such as the screw, expeller, and piston configurations) work better for specific algae types. Often, mechanical crushing is used in conjunction with chemical solvents.

Ultrasonic extraction is a type of physical extraction that can greatly accelerate extraction processes. Using an ultrasonic reactor, ultrasonic waves are used to create cavitation bubbles in a solvent material. When these bubbles collapse near the cell walls, the resulting shock waves and liquid jets cause those cells walls to break and release their contents into a solvent. Ultrasonication can enhance basic enzymatic extraction. The combination sono-enzymatic treatment accelerates extraction and increases yields.

In chemical extraction, chemical solvents are often used in the extraction of the oils. A common choice of chemical solvent is hexane, although other hydrocarbon solvents can also be used. Another method of chemical solvent extraction is Soxhlet extraction in which oils from the algae are extracted through repeated washing, or percolation, with an organic solvent, under reflux in specialized equipment. The value of this technique is that the solvent is reused for each cycle.

Supercritical carbon dioxide can also be used as a solvent. In this method, carbon dioxide is liquefied under pressure and heated to the point that it becomes supercritical (having properties of both a liquid and a gas), allowing it to act as a solvent.

Enzymatic extraction uses enzymes to degrade the cell walls with water acting as the solvent. This makes fractionation of the oil much easier. The enzymatic extraction can be supported by ultrasonication.

See Algae, Algae Fuels, Aquatic Plants, Biomass.

Algal Blooms

Algal blooms refer to the rampant growth of certain microalgae, which in turn leads to the production of toxins, disruption of the natural aquatic ecosystems, and increases the costs of water treatments. The blooms take on the colors of the algae contained within them. Graham states that the main toxin producers in oceans are certain dinoflagellates

and diatoms. In freshwaters, cyanobacteria are the main toxin producers, though some eukaryotic algae also cause problems. Under natural conditions, Graham notes that algae use the toxins to protect themselves from being eaten by small animals and only need a small amount to protect themselves.

The main cause of algal blooms is nutrient pollution in which there is an excess of nitrogen and phosphorus, which can push algae toward unrestrained growth. The phenomenon is caused by a variety of human activities in which the fertilizers used in agriculture and animal manures are rich in nitrogen, while improperly treated wastewater is high in both nitrogen and phosphorus.

Alkali Washing Process

Alkali washing (often referred to as caustic scrubbing) for hydrogen sulfide removal with caustic scrubbing is only economical in small amounts if hydrogen sulfide is present and suitable means of disposing the spent solution are available. The chemistry is simple and to some extent, depending upon the concentration of hydrogen sulfide in the gas stream, efficient. Thus:

Carbonate washing is a mild alkali process for emission control by the removal of acid gases (such as carbon dioxide and hydrogen sulfide) from gas streams and uses the principle that the rate of absorption of carbon dioxide by potassium carbonate increases with temperature. It has been demonstrated that the process works best near the temperature of reversibility of the reactions:

In the Benfield process, acid gases are scrubbed from the feed in an absorber column using potassium carbonate solution with Benfield additives to improve performance and avoid corrosion.

Water washing, in terms of the outcome, is analogous to washing with potassium carbonate (Kohl and Riesenfeld, 1985), and it is also possible to carry out the desorption step by pressure reduction. The absorption is purely physical, and there is also a relatively high absorption of hydrocarbon derivatives, which are liberated at the same time as the acid gases.

Alicyclic Hydrocarbons

Alicyclic hydrocarbons contain cyclic structures in all or part of the chemical skeleton. The saturated alicyclic hydrocarbons have the general formula C_nH_{2n} . When the molecular formula of a saturated hydrocarbon corresponds to the general formula $\text{C}_n\text{H}_{2n-2}$, then the compound contains two rings; if the formula corresponds to $\text{C}_n\text{H}_{2n-4}$, it contains three rings, etc. Their boiling points and densities are higher than alkanes having the same number of carbon atoms. In crude oil, the most frequently found rings are those having five or six carbon atoms. In these rings, each hydrogen atom can be substituted by a paraffinic alkyl chain that is either a straight chain or branched. Monocyclic naphthenes with one ring are major constituents of the light fraction. Monocyclic naphthene of carbon numbers C_{20} to C_{30} , with long side chains can be isolated from paraffin waxes.

Cycloalkanes (naphthenes) catalytically crack by both ring and chain rupture and yield olefins and paraffin. In the case of hydrocracking process, polycyclic hydrocarbons aromatic are partially hydrogenated. Naphthene rings in polycyclic compounds are readily removed by ring-opening followed by cracking. Single-ring naphthenes and paraffin are more resistant to cracking. It was also found that single-ring naphthenes appear to react more slowly at high conversion levels. In the catalytic reforming process, the fundamental reaction occurring is (i) dehydrogenation of six members rings naphthenes by platinum catalyst, and (ii) isomerization of alkyl cyclopentane derivatives to cyclohexane derivatives.

The stability of the cycloalkane derivatives increases up to the six member ring, then decreases from seven to eleven member ring, and from the twelve member onwards attains the stability of two six member rings (Table A-12).

Table A-12 Properties of selected alicyclic hydrocarbon derivatives.

Alicyclic hydrocarbon (naphthene)	Melting point, °C	Boiling point, °C	Density, @20 °C
Cyclopropane	-127	-33	
Cyclobutane	-80	13	
Cyclopentane	-94	49	0.746
Cyclohexane	6.5	81	0.778
Cycloheptane	-12	118	0.810
Cyclooctane	14	149	0.830
Methylcyclopentane	-142	72	0.749
Cis-1,2- dimethylcyclopentane	-62	99	0.772
Trans-1,2- dimethylcyclopentane	-120	92	0.750
Methylcyclohexane	-126	100	0.769

Aliphatic Hydrocarbons

Aliphatic hydrocarbon derivatives (also known as paraffins or paraffin derivatives) are straight chain or branched saturated organic compounds with composition $C_n H_{2n+2}$. Paraffin derivatives are present in large amounts in nature and low molecular weight paraffin derivatives are found in natural gas. Methane is the lowest member of the paraffin series of hydrocarbons. With the increase in size of molecule, several hydrocarbons may exist. Such hydrocarbons have different properties and are known as isomers. On the other hand, olefin hydrocarbon derivatives have carbon atoms joined by two bonds.

Hydrocarbon derivatives are classified into chemical families according to their structure. All structures are members of the homologous series of even hydrogen numbers. The chemical formula is $C_n H_{2n+2}$ or lower in hydrogen content $C_n H_{2n}$. The carbon-carbon molecule chains have different chemical bonding arrangements such as (i) saturated hydrocarbon derivatives that are linked by carbon-carbon single bonds and are given the suffix *ane* and (ii) unsaturated hydrocarbon derivatives that are linked by multiple bonds double bond $C=C$ (suffix *ene*) or triple $C\equiv C$ (suffix *yne*). However, the same molecule can contain several multiple bonds – if there are two low sets of the double bond, the suffix is *diene*.

Normal alkanes (straight-chain paraffins) consist of a chain of carbon atoms. Each carbon atom is linked to four atoms, which can be either carbon or hydrogen, their general formula $C_n H_{2n+2}$. The carbon skeleton can be structured as straight chains as are the normal paraffin, $CH_3(CH_2)_n CH_3$. The boiling points increase with the number of carbon atoms. With the low carbon numbers, the addition of a carbon increases the boiling point to approximately 25°C. Further additions give smaller increase. At the same time, the density increases with the molecular weight 0.626 kg/L for pentane, and 0.791 kg/L for pentacosane; on the other hand, the density is always much lower than 1. The normal alkanes from C_1 to C_4 are colorless gases; C_5 to C_{17} colorless liquids; and from C_{18} onwards, colorless solids. Other physical properties, such as melting point, density, and viscosity, also increase in the same way as boiling point (Table A-13). There is a relationship between physical properties and chemical composition. The variation in boiling point of compounds is due to different intermolecular forces such as hydrogen bonding. The alkanes are insoluble in water.

Table A-13 Physical properties of n-paraffins.

Alkane	Melting point, °C	Boiling point, °C	Density, g/ml @20°C
Methane	-183	-162	
Ethane	-172	-88.5	
Propane	-167	-42	
Butane	-138	0	
Pentane	-130	36	0.626
Hexane	-95	69	0.659
Heptane	-90	98	0.684
Octane	-57	126	0.703
Nonane	-54	151	0.718
Decane	-30	174	0.730
Undecane	-26	196	0.740
Dodecane	-10	216	0.749
Tridecane	-6	234	0.757
Tetradecane	5.5	252	0.764
Pentadecane	10	266	0.769
Hexadecane	18	280	0.775
Heptadecane	22	292	
Octadecane	28	308	
Nonadecane	32	320	

Isoparaffins (Table A-14) are paraffins in which branching is present, usually at the number 2 carbon atom, although branching can take place at a different position in the chain, although such molecules are not strictly isoparaffins. Isoparaffins (branched paraffins) have a boiling point lower than normal paraffin with same number of carbon atoms, and generally, the greater the branching, the lower the boiling point (Table A-14).

Table A-14 Physical properties of selected branched paraffins.

Paraffin	Melting point, °C	Boiling point, °C	Density, g/ml @20 °C
Isobutane	-159	-12	
Isopentane	-160	28	0.620
Neopentane	-17	9.5	
Isohexane	-154	60	0.654
3-Methylbutane	-118	63	0.676
2,2-Dimethylbutane	-98	50	0.649
2,3-Dimethylbutane	-129	58	0.668

Octane number is a measure of the ability of a fuel (gasoline) to avoid knocking. The test engine is adjusted to give knock from the fuel rated. Then, various mixtures of isooctane (2,2,4-trimethylpentane) and n-heptane are used to find the ratio of the two reference fuels that will give the same intensity knock as that from unknown fuel. Defining isooctane as having an octane number of 100 and n-heptane as 0, the octane number is the volumetric percentage of isooctane in heptane that matches knock from the unknown fuel is reported as octane number of the fuel.

Unsaturated aliphatic hydrocarbon derivatives (olefin derivatives) (Table A-15) have one or more double bonds between carbon atoms. Also, olefin derivatives have different types of isomers – for example, butene (C_4H_8) isomers have many arrangements which include 1-butene ($CH_3CH_2CH=CH_2$), cis 2-butene (cis- $CH_3CH=CHCH_3$), trans 2-butene (trans- $CH_3CH=CHCH_3$), and isobutene [$(CH_3)_2CH=CH_2$].

Table A-15 Physical properties of selected olefins.

Olefin	Melting point, °C	Boiling point, °C	Density, g/ml @20°C
Ethylene	-169	-102	
Propylene	-158	-48	
1-Butene		-6.5	
1-Pentene		30	
1-Hexene	-138	63.5	0.643
1-Heptene	-119	93	0.675
1-Octene	-104	122.5	0.698
1-Nonene		146	0.716
1-Decene	-87	171	0.731
Cis-2-butene	-139	4	0.743
Trans-2-butene	-106	1	
Isobutylene	-141	-7	
Cis-2-pentene	-151	37	
2-Methyl-2-butene	-123	39	0.655
2,3-Dimethyl-2-butene	-74	73	0.660
Cyclopentene	-93	46	0.705
Cyclohexene	-104	83	0.774
1,3-Cyclopentadiene	-85	42	0.810
1,3-Cyclohexadiene	-49	87	0.798
			0.847

Owing to the presence of a double bond, the alkene undergoes a large number of addition reactions, but under special conditions, they also undergo substitution reactions. Alkene is readily hydrogenated under pressure in the presence of a catalyst. Platinum and palladium are effective at room temperature. Addition polymerization occurs between molecules containing double or triple bonds. The following are some reactions of aliphatic hydrocarbons to enhance its properties.

See also: Alkanes, Alkenes.

Alkalinity

Alkalinity is a measure of the ability of a solution to neutralize acids to the equivalence point of carbonate or bicarbonate. Alkalinity is closely related to the acid neutralizing capacity (ANC) of a solution, and it is the acid neutralizing capacity that is often incorrectly used to refer to alkalinity.

The alkalinity of a system is equal to the stoichiometric sum of the bases in solution. In the natural environment, carbonate alkalinity tends to make up most of the total alkalinity due to the common occurrence and dissolution of carbonate rocks and presence of carbon dioxide in the atmosphere.

Alkalinity is sometimes incorrectly used interchangeably with basicity as when the pH of a solution can be lowered by the addition of carbon dioxide. This will reduce the basicity; however, the alkalinity will remain unchanged.

Alkaloids

Alkaloids are a class of nitrogenous organic compounds of plant origin which have pronounced physiological actions on humans and include many drugs (morphine, quinine) and poisons (atropine, strychnine). Alkaloids are naturally occurring chemical compounds containing basic nitrogen atoms and are produced by a large variety of organisms, including bacteria, fungi, plants, and animals.

The alkaloids are perhaps the last class of organic compounds which originate in plants that are of any importance in the formation of the organic substance of coal. These compounds all contain basic nitrogen in the molecule with the nitrogen frequently occurring in a cyclic system; in addition, most of the alkaloids also contain oxygen functions.

Alkaloids are biologically active, organic compounds that contain a nitrogen atom which compounds have many structural frameworks, and are therefore highly variable. Alkaloids occur in the roots, bark, leaves, and within the cells of many plants. The structural chemistry of the alkaloids is variable because of the many locations in which nitrogen can occur in organic systems. However, it is generally recognized that the alkaloids may be based on any one of several individual (or even on a combination of two or more) systems.

Alkaloids are divided into the several large groups, such as pyrrolidine, pyridine, quinoline, isoquinoline, indole, and quinazoline. They are often divided into main groups including peptides and cyclopeptide alkaloids, and true-alkaloids, proto-alkaloids, polyamine-alkaloids, and pseudo-alkaloids. Although most alkaloids are pharmacologically active or poisonous in high doses, there are some alkaloids in foods that are often consumed daily, of which the common examples are caffeine, theobromine, and theophylline (members of the purine alkaloid family) which are mainly found in coffee, cocoa beans, and tea leaves.

Alkaloids have been isolated as crude extracts from plants for many millennia as part of folk medications. However, since the 20th Century, individual alkaloids with defined and scientifically verified pharmacological properties have been purified and produced commercially as fine chemicals.

The complexity of the chemical structures of the alkaloids makes them, in most cases, impossible to produce by chemical synthesis, so extraction from a crude plant mixture remains the most economically viable strategy. However, plants normally produce complex mixtures of alkaloids (rather than a single alkaloid) with the desirable types often at low levels, with the result that commercially produced specific alkaloids are expensive. As the genetic manipulation of plants becomes more sophisticated, research has focused on the engineering of alkaloid biosynthesis to generate transgenic or cell lines that overproduce specific alkaloids. This can be achieved by increasing the synthesis of a particular alkaloid and/or inhibiting the synthesis of related compounds to increase the ease of purification.

Alkanes

Alkanes (sometimes referred to as paraffins or paraffin hydrocarbons) are aliphatic hydrocarbons (non-aromatic hydrocarbon derivatives) that contain carbon and hydrogen only in which all of the binding orbitals of the carbon atoms are satisfied by bonding to another carbon atom or to a hydrogen atom.

Normal alkanes (straight-chain paraffins) consist of a chain of carbon atoms. Each carbon atom is linked to four atoms, which can be either carbon or hydrogen, their general formula C_nH_{2n+2} (Table A-16). The carbon skeleton can be structured as straight chains as are the normal paraffin, $CH_3(CH_2)_nCH_3$. The boiling points increase with the number of carbon atoms. With the low carbon numbers, the addition of a carbon increases the boiling point by approximately 25°C (77°F). Further additions give smaller increase. At the same time, the density increases with the molecular weight 0.626 kg/L for pentane, and 0.791 kg/L for pentacosane; on the other hand, the density is always much lower than 1. The normal alkanes from C_1 to C_4 are colorless gases; C_5 to C_{17} colorless liquids; and from C_{18} onwards, colorless solids. Other physical properties, such as melting point, density, and viscosity, also increase in the same way as boiling point. There is a relationship between physical properties and chemical composition. The variation in the boiling point of compounds is due to different intermolecular forces such as hydrogen bonding. The alkanes are insoluble in water.

Table A-16 Physical properties of n-paraffins.

Alkane	Melting point, °C	Boiling point °C	Density, g/ml @20°C
Methane	-183	-162	
Ethane	-172	-88.5	
Propane	-167	-42	
Butane	-138	0	
Pentane	-130	36	0.626

Paraffins	Melting point, °C	Boiling point, °C	Density, g/ml @20 °C
Isobutane	-159	-12	
Isopentane	-160	28	0.620
Neopentane	-17	9.5	
Isohexane	-154	60	0.654
3-Methylbutane	-118	63	0.676
2,2-Dimethylbutane	-98	50	0.649
2,3-Dimethylbutane	-129	58	0.668

The octane number is a measure of the ability of a fuel (gasoline) to avoid knocking. The test engine is adjusted to give knock from the fuel rated. Then, various mixtures of isooctane (2,2,4-trimethylpentane) and n-heptane are used to find the ratio of the two reference fuels that will give the same intensity knock as that from unknown fuel. Defining isooctane as 100 octane number and n-heptane as 0, the octane number is the volumetric percentage of isooctane in heptane that matches knock from the unknown fuel is reported as the octane number of the fuel.

Alkanolamines

The removal of acid gases by the alkanolamine process (*amine process*) is accomplished by a chemical reaction. Physical solvents (Selexol, Sulfinol, Propylene Carbonate) remove acid gases by straight absorption or a combination of absorption and chemical reaction.

The alkanolamine can be categorized on a chemical basis as being primary (MEA, DGA), secondary (DEA, DIPA), and tertiary (MDEA, TEA) depending on the number of substitutions onto a central nitrogen atom. Solvents currently in use include formulated MDEA (Ucarsol, Gas Spec) and hindered amines (FLEXSORB). This chemical structure influences each properties of the alkanolamine as a treating solvent and therefore, lend themselves to different applications.

Furthermore, the following is a list of conditions must be defined when selecting a treating solvent: (i) the operating pressure and temperature, (ii) the amount of acid gases and quantity removed, selectivity, and treated gas specifications, (iii) the disposal of the acid gases such as sulfur recovery and/or incineration, (iv) the contaminants in the inlet gas, such as oxygen, mercaptans and other sulfur species, free liquids, and gas composition, and (v) the environment, such as spill reporting and allowable ambient sulfur oxide emission.

Alkazid Process

The Alkazid process is a process for the removal of hydrogen sulfide and carbon dioxide from gas streams using concentrated aqueous alkaline (caustic) solutions of amino acids. The process is used primarily to treat gas of high sulfur content before it goes to other stops for more complete purification. It also claimed the advantage of yielding hydrogen sulfide of high concentration of up to 90% hydrogen sulfide. The process has been used to treat gas containing up to 10% v/v hydrogen sulfide and removes the hydrogen sulfide to 0.07 to 0.10% v/v. The process is also used for low pressure CO₂ removal where sulfur is not present or is present in small quantities.

In the process, the purified gas stream leaves the unit from the top of the absorber or absorbers and the cold lean alkaline solution passes countercurrent to the gas down the columns, out the bottom through a screen and is pumped through a heat exchanger countercurrent to the hot lean caustic from the bottom of the stripper. From the heat exchanger, the rich alkaline solution is fed to the top of the stripper column. The stripper kettle temperature is maintained at approximately 105°C (220°F). The stripped gas (hydrogen sulfide and carbon dioxide) leaves the top of the stripper, and passes through a condenser and separator to remove condensate, thence out of the system to the Claus Unit or other disposal system.

The steam to heat the kettle of the stripper is distributed between direct and indirect heating in order to hold the specific gravity of the alkaline solution between 1.16 and 1.20. If the gravity of the solution gets too high or the solution gets too cold, solids will settle out. The stripped caustic leaves the bottom of the absorber through a screen, passes through the countercurrent heat exchange mentioned above, through a water cooler and to the top of the absorber.

There are two types of solutions used in the Alkazid process: (i) the DIK caustic version – the solution most commonly used – is a solution of potassium dimethyl or diethyl alpha amino-acetate and is used to remove hydrogen sulfide from gases containing carbon disulfide, and (ii) the M-caustic version which uses a solution of potassium methyl alpha amino-propionate which absorbs both hydrogen sulfide and carbon dioxide but is used only in the absence of carbon disulfide. The usual effective gas charge of the solutions ranges from 10 to 15 volumes per volume of caustic for best removal of hydrogen sulfide but can be increased to as much as 30 to 35 volumes per volume by use of mechanical contacting devices and longer contact time, or by permitting higher sulfur content in the outlet gas.

Absorption and stripping are at substantially atmospheric pressure, and the optimum absorption temperature is approximately 5°C (41°F), but a temperature up to 30°C (86 °F) can be used satisfactorily. The relative absorption of carbon dioxide by the DIK-caustic version increases with increased absorption temperature, and with increased time of contact over the normal 1 minute. Any oxygen that enters the system during the operation forms thiosulfates in the solution, destroying its effectiveness. Special precautions are taken to prevent air entering the system at pump packing, or in the solution storage vessels, etc. This difficulty limits the use of the process to oxygen-free gases.

Alkenes

An alkene (olefin) is an unsaturated chemical compound containing at least one carbon-to-carbon double bond (Table A-18). The simplest acyclic alkenes, with only one double bond and no other functional groups, form a homologous series of hydrocarbons with the general formula C_nH_{2n} . The simplest alkene is ethylene (C_2H_4), which has the International Union of Pure and Applied Chemistry (IUPAC) name ethene. Alkenes are also called olefins (an archaic synonym, widely used in the petrochemical industry).

The physical properties of alkenes are comparable with those of alkanes (aliphatic hydrocarbons). The physical state depends on molecular mass (gases from ethylene to butene - liquids from pentene onwards). The simplest alkenes, ethylene, propylene (propene), and butylene (butene) are gases. Linear alkenes of approximately 5 to 16 carbons are liquids, and higher molecular weight alkenes are waxy solids. Alkenes are more reactive than alkanes due to the presence of a carbon-carbon pi-bond (double bond). The majority of the reactions of alkenes involve the rupture of this pi bond, forming new single bonds.

Table A-18 Physical properties of selected olefins.

Olefin	Melting point, °C	Boiling point, °C	Density, g/ml @20 °C
Ethylene	-169	-102	
Propylene	-158	-48	
1-Butene		-6.5	
1-Pentene		30	
1-Hexene	-138	63.5	0.643
1-Heptene	-119	93	0.675
1-Octene	-104	122.5	0.698
1-Nonene		146	0.716
1-Decene	-87	171	0.731
Cis-2-butene	-139	4	0.743
Trans-2-butene	-106	1	
Isobutylene	-141	-7	
Cis-2-pentene	-151	37	
2-Methyl-2-butene	-123	39	0.655
2,3-Dimethyl-2-butene	-74	73	0.660
Cyclopentene	-93	46	0.705
Cyclohexene	-104	83	0.774
1,3-Cyclopentadiene	-85	42	0.810
1,3-Cyclohexadiene	-49	87	0.798
			0.847

Alkenes serve as a feedstock for the petrochemical industry because they can participate in a wide variety of reactions.

The simplest acyclic alkenes, with only one double bond and no other functional groups, form a homologous series of hydrocarbons with the general formula C_nH_{2n} .

The physical properties of alkene derivatives are comparable with those of alkane derivatives (aliphatic hydrocarbon derivatives). The physical state depends on molecular mass (gases from ethylene to butene and liquids from pentene onwards). The simplest alkenes, ethylene, propylene (propene), and butylene (butene) are gases. Linear alkenes of approximately 5 to 16 carbons are liquids, and higher molecular weight alkenes are waxy solids.

Alkene derivatives are more reactive than alkane derivatives due to the presence of a carbon-carbon pi-bond (double bond). The majority of the reactions of alkenes involve the rupture of this pi bond, forming new single bonds.

Alpha Decay

Alpha decay (α -decay) is the radioactive emission of an α -particle which is the nucleus of helium-4 (^4He), consisting of two protons and two neutrons which is a stable nucleus as it is doubly magic. The daughter nucleus has two protons and four nucleons fewer than the parent nucleus. In general, alpha decay leads to the ground state of the daughter nucleus so that the emitted particle carries away as much energy as possible.

By way of definition, a nucleon is either a proton or a neutron considered in its role as a component of an atomic nucleus. The number of nucleons in a nucleus defines the mass number (the nucleon number) of an isotope. In fact, protons and neutrons are best known in their role as nucleons, i.e., as the components of atomic nuclei, but they also exist as free particles. Free neutrons are unstable, with a half-life of approximately 13 minutes, but they have important applications. Protons not bound to other nucleons are the nuclei of hydrogen atoms when bound with an electron or – if not bound to anything – are ions or cosmic rays. Both the proton and the neutron are composite particles insofar as each is composed of smaller parts and, thus, neither the proton nor the neutron is an elementary particle.

A pertinent example from the area of nuclear energy is the decay of uranium-238 (^{238}U) to thorium-234 (^{234}Th). An alpha particle (also called alpha rays or alpha radiation) has a charge of $+2e$, but, as a nuclear equation, describes a nuclear reaction without considering the electrons and consists of two protons and two neutrons bound together into a particle identical to a helium-4 (^4He) nucleus and are typically the product of the alpha decay process. The symbol for the alpha particle is α or α^{2+} , and because alpha particles are identical to helium nuclei, they are also sometimes written as He^{2+} or $^4_2\text{He}^{2+}$ which indicates a helium ion with a +2 charge (missing two electrons). Once the ion gains electrons from its environment, the alpha particle becomes a normal (electrically neutral) helium atom ^4_2He .

Alpha decay typically occurs in the heaviest nuclides, and, theoretically, it can occur only in nuclei somewhat heavier (higher atomic number) than nickel atomic (number = element 28), where the overall binding energy per nucleon is no longer a minimum and the nuclides are therefore unstable toward spontaneous fission-type processes. In practice, this mode of decay has only been observed in nuclides considerably heavier than nickel, with the lightest known alpha emitters being the lightest isotopes (mass numbers 104 to 109) of tellurium (atomic number = element 52).

When an atom emits an alpha particle in alpha decay, the mass number of the atom decreases by four due to the loss of the four nucleons in the alpha particle. The atomic number of the atom decreases by two, as a result of the loss of two protons, and the atom becomes a new element. Also, unlike other types of decay, alpha decay as a process must have a minimum-size atomic nucleus that can support it. The process may leave the nucleus in an excited state after which the emission of a gamma ray then removes the excess energy.

See also: Beta Decay, Gamma Decay, Nuclear Energy.

Alpha Particle

An alpha particle (also termed alpha radiation or alpha rays) is a helium nucleus stripped of its orbital electrons and which is emitted from a radioactive atom with a velocity of about 1/20 that of the speed of light and with energies ranging from 4 to 9 MeV. The alpha particle was the first nuclear radiation to be discovered; beta particles and gamma rays were identified soon thereafter.

Alpha particles cause ionizations in matter when they are deflected by the positive charge of a nucleus and pull the orbital electrons (attracted by the alpha's positive charge) along with them. Alpha particles also cause excitation along their path by pulling inner orbital electrons to outer orbits. Energy is then given off by the atom as fluorescent radiation (low energy x-rays) when the electrons drop back down to the inner orbital vacancies.

Because of its relatively large mass (2 neutrons and 2 protons), high electrical charge (2+) and low velocity, the specific ionization of an alpha particle is high and, as a result, it creates many ion pairs in a very short path length. Because of this, it loses all of its energy in a short distance. The range in air is only several centimeters even for the most energetic alpha particles.

Alpha particles are highly ionizing because of the double positive charge, large mass (compared to a beta particle), and because they are relatively slow. They can cause multiple ionizations within a short distance which gives

alpha particles the potential to do much more biological damage for the same amount of deposited energy. Alpha particles cannot penetrate the normal layer of dead cells on the outside of our skin but can damage the cornea of the eye. Alpha-particle radiation is normally only a safety concern if the radioactive decay occurs from an atom that is already inside the body or a cell. Alpha-particle emitters are particularly dangerous if inhaled, ingested, or if they enter a wound. Once inside the body, surrounded by living tissue, damage will be to the local area in which the alpha emitter is deposited. Thus, alpha emitters are an internal hazard and intake to the body must be prevented.

Alternate Fuels

Alternate fuels (renewable fuels, advanced fuels, synthetic fuels which include liquid and gaseous fuels, as well as clean solid fuels) are any materials or substances that can be used as fuels, other than conventional fuels. Alternate fuels are derived from resources such as coal, oil shale, or tar sands, and various forms of biomass – in the last case the term that is more appropriate is renewable fuels. Renewable fuels are making headway into the fuel balance by reducing dependence on imported oil. Often, renewable fuels produce less pollution than crude oil-derived gasoline or crude oil-derived diesel fuel.

Examples of renewable fuels and renewable energy sources are: (i) biodiesel, which is diesel fuel derived from vegetable oils and animal fats. It usually produces less air pollutants than crude oil-based diesel, (ii) biogas which is produced from the anaerobic digestion of diverse organic waste sources using various methods, (iii) biomass liquids: produced by biomass-to-gas-to-liquid conversion and by pyrolysis processes which involve the conversion of biomass, such as wood and agricultural residues, (iv) ethanol or other alcohols produced domestically from corn and other crops and produces less greenhouse gas emissions than conventional fuels, and (v) hydrogen which is produced from biomass, (vi) nuclear power, or (vii) other sources such as solar energy, tidal energy, and wind energy and hydroelectric power.

Biodiesel from plant sources is similar to diesel, but has differences that include higher cetane rating (45 to 60 compared to 45 to 50 for crude oil-derived diesel fuel), and it acts as a cleaning agent to get rid of dirt and deposits. As with alcohols and gasoline engines, taking advantage of the high cetane number of biodiesel potentially overcomes the energy deficit compared to ordinary number 2 diesel.

See also: Biodiesel, Biogas, Hydrogen, Synthetic Fuel.

Alternate Fuels – Gaseous Fuels

Gaseous fuels are those fuels that are in the gaseous state under ambient conditions. In some circumstances, the definition of gaseous fuels may also include the low-boiling hydrocarbons such as pentane but such fuels are considered to be liquid fuels.

Biogas (i.e., gas from biological or alternate sources) is a clean and renewable form of energy, and the most important biogas components are methane (CH_4), carbon dioxide (CO_2), and sulfuric components (H_2S). The gas is generally composed of methane (55 to 65%), carbon dioxide (35 to 45%), nitrogen (0 to 3%), hydrogen (0 to 1%), and hydrogen sulfide (0 to 1%). Biogas could very well substitute for conventional sources of energy (i.e., fossil fuels) which are causing ecological–environmental problems and at the same time depleting at a faster rate. Due to its elevated methane content, resultant of the organic degradation in the absence of molecular oxygen, biogas is an attractive source of energy. The physical, chemical, and biological characteristics of the manure are related to diet composition, which can influence the biogas composition. Raw natural gas is approximately 70 to 95% methane, but biogas is approximately 55 to 65% methane. The biogas composition is an essential parameter because it allows identifying the appropriate purification system, which aims to remove sulfuric gases and decrease the water volume, contributing to improve the combustion fuel conditions.

Currently, biogas production is mainly based on the anaerobic digestion of single energy crops. Maize, sunflower, grass, and Sudan grass are the most commonly used energy crops. In the future, biogas production from energy crops will increase and requires to be based on a wide range of energy crops that are grown in versatile, sustainable crop rotations.

A specific source of biogas is landfills. In a typical landfill, the continuous deposition of solid waste results in high densities and the organic content of the solid waste undergoes microbial decomposition. The production of methane rich landfill gas from landfill sites makes a significant contribution to atmospheric methane emissions. In many situations, the collection of landfill gas and production of electricity by converting this gas in gas engines is profitable and the application of such systems has become widespread. The benefits are obvious: useful energy carriers are produced from gas that would otherwise contribute to a buildup of methane in the atmosphere, which has stronger greenhouse gas impact than the carbon dioxide emitted from the power plant. This makes landfill gas utilization in general an attractive greenhouse gas mitigation option, which is being increasingly deployed in world regions.

In summary, biogas is most commonly produced by using animal manure mixed with water, which is stirred and warned inside an airtight container, known as a digester. The most important biogas components are methane, carbon dioxide, and sulfuric components. The gas generally composes of methane (55 to 65%), carbon dioxide (35 to 45%), nitrogen (0 to 3%), hydrogen (0 to 1%), and hydrogen sulfide (0 to 1%).

Anaerobic processes could either occur naturally or in a controlled environment such as a biogas plant. Organic waste such as livestock manure and various types of bacteria are put in an airtight container called digester so that the process could occur. In the complex process of anaerobic digestion, hydrolysis/acidification and methanogenesis are considered as rate-limiting steps.

Most biomass materials are easier to gasify than coal because they are more reactive with higher ignition stability. This characteristic also makes them easier to process thermochemically into higher-value fuels such as methanol or hydrogen. Ash content is typically lower than for most coals, and sulfur content is much lower than for many fossil fuels. Unlike coal ash, which may contain toxic metals and other trace contaminants, biomass ash may be used as a soil amendment to help replenish nutrients removed by harvest. A few biomass feedstocks stand out for their peculiar properties, such as high silicon or alkali metal contents – these may require special precautions for harvesting, processing, and combustion equipment. Note also that mineral content can vary as a function of soil type and the timing of feedstock harvest. In contrast to their fairly uniform physical properties, biomass fuels are rather heterogeneous with respect to their chemical elemental composition.

A number of processes allow biomass to be transformed into gaseous fuels such as methane or hydrogen. One pathway uses algae and bacteria that have been genetically modified to produce hydrogen directly instead of the conventional biological energy carriers. Problems are intermittent production, low efficiency, and difficulty in constructing hydrogen collection and transport channels of low cost. A second pathway uses plant material such as agricultural residues in a fermentation process leading to biogas from which the desired fuels can be isolated. This technology is established and in widespread use for waste treatment, but often with the energy produced only for onsite use, which often implies less than maximum energy yields. Finally, high-temperature gasification supplies a crude gas, which may be transformed into hydrogen by a second reaction step. In addition to biogas, there is also the possibility of using the solid by-product as a biofuel.

The technologies for gas production from biomass include processes such as (i) fermentation, (ii) gasification, and (iii) direct biophotolysis.

See also: Gaseous Fuels.

Alternate Fuels – Liquid Fuels

Liquid fuels are combustible or energy-generating molecules that can be harnessed to create mechanical energy. It is the fumes of liquid fuels that are flammable instead of the fluid. Most liquid fuels in widespread use are derived from fossil fuel sources, but there are several types derived from non-fossil fuel sources – these are hydrogen, methanol ethanol, and biodiesel that are derived from non-fossil fuel sources which are also categorized as a liquid fuel.

Biofuel is a generic name for gaseous, liquid, or solid fuels that are not derived from fossil fuels or contain a proportion of non-fossil fuel. For the purposes of this text, the term alternate fuels is used to represent those fuels that are produced from plant sources as well as from other sources such as the organic constituents' (predominantly biological in nature) municipal and industrial waste. Thus, biofuels are *bio-materials* that are produced made from renewable biological sources which are now contemplated as grown specifically for the purpose of providing useful

heat upon combustion. Biofuels are produced from sources such as: corn, soybeans, flaxseed, rapeseed, sugarcane, palm oil, sugar beet raw sewage, food scraps, animal parts, and rice.

Biofuels are fuels derived from plant materials – are entering the market, driven by factors such as oil price spikes and the need for increased energy security. Examples of solid biofuels include wood, sawdust, grass cuttings, domestic refuse, charcoal, agricultural waste, non-food energy crops, and dried manure. Biofuels are also known as non-conventional fuels or alternative fuels. Alternative fuels can be classified as any fuel that is not derived from conventional sources like natural gas, crude oil, and coal.

See also: Liquid Fuels.

Alternate Fuels - Production

Biorenewable feedstocks can be converted into liquid or gaseous forms for the production of electric power, heat, chemicals, or gaseous and liquid fuels. Main biomass conversion processes are – alphabetically rather than by preference – (i) anaerobic digestion, (ii) direct combustion, (iii) fermentation, (iv) gasification, and (v) pyrolysis. Each process has its own particular aspects, and process application is dependent upon the type of feedstock and the desired product(s).

The amount of hemicellulose and cellulose in wood and the chemical products desired determine the general type of process that might be used to hydrolyze wood. Hardwoods yield more five-carbon sugars than softwoods. Since, at this time, only the six-carbon sugars from cellulose are readily fermentable, softwoods are desired for ethanol production, but they are not as widely available as hardwoods. Hardwoods are more widely available now, so considerable effort has been expended to develop processes to utilize their unique constituents.

The main components of wood cells are cellulose (an insoluble substance which is the main constituent of plant cell walls and of vegetable fibers such as cotton. It is a polysaccharide consisting of chains of glucose monomers.), hemicellulose (a class of substances which occur as constituents of the cell walls of plants and are polysaccharides of simpler structure than cellulose.), and lignin (a complex organic polymer deposited in the cell walls of many plants, making them rigid and woody), forming some 99 % w/w of the wood material. Cellulose and hemicellulose are formed by long chains of carbohydrates, whereas lignin is a complicated component of polymeric phenolics. Lignin is rich in carbon and hydrogen, which are the main heat producing elements. Thus, the calorific value of lignin is higher than that of cellulose and hemicellulose (both are carbohydrate derivatives). Wood and bark also contain so-called extractives, such as terpenes, fats, and phenols. The amount of wood extractives is relatively small compared to the amount of extractives from bark and foliage.

The nitrogen (N) content of wood is approximately 0.75 %, varying somewhat from one tree species to another. For example, nitrogen-fixing alder (*Alnus* sp.) contains twice as much nitrogen as most coniferous trees. Wood has practically no sulfur (S) and, compared to many other fuels, the wood has a relatively low carbon content (some 50% of the dry weight) and high oxygen content (some 40% w/w), which leads to relatively low heating value per dry weight.

The collection of solid wastes is usually organized on a communal basis; in developing countries though, it may be organized (to a greater or lesser extent) on an informal basis. The treatment and disposal of solid wastes are definitely connected. Treatment is applied to recover useful substances or energy, to reduce waste volume, or to stabilize waste remains to be dumped or disposed of in landfills. Wastes may be treated before disposal to reduce the volume or to alter the characteristics of the waste which can be achieved by various physical, chemical, and biological processes, while combustion can be used to destroy some toxic organic chemicals. Where a method of waste disposal is not specified, the choice of disposal route will typically depend on (i) the availability of facilities, (ii) volume of waste material, and (iii) hydro-geological characteristics; the influence of industrial and environmental lobby groups must also be taken into account.

Provided that there is no shortage of land with suitable geological formations, landfill remains the principal final disposal route for the majority of wastes, even in highly industrialized countries. Where there is treatment, it is usually designed to reduce the volume of waste to be landfilled and includes compaction, shredding, baling, and combustion. Most solid wastes will therefore directly be disposed of in sanitary landfills.

The prefix *sanitary* is mainly to be understood as providing some protection for the population against airborne dust and litter, stench, rodents, and insects. Most of these nuisances can be prevented by the prompt covering of

freshly dumped waste with soil. However, to be able to call a waste tip or landfill *sanitary* from an environmental viewpoint requires more measures to be taken. The main environmental problem associated with landfilling is pollution of groundwater. Rainwater percolating through solid waste tends to carry large amounts of pollutants to groundwater aquifers if the underlying strata are pervious or fissured. Thus, wells drawing from the aquifers will be extracting groundwater contaminated by the leachate; such a situation is often difficult to remedy. Studies have shown that the leachate from solid wastes may have a pollution load up to 15 to 20 times higher than domestic wastewater.

Landfill tends to predominate as a waste disposal mode because it is regarded as an effective but low-cost method of disposal, also for hazardous waste. Even where other methods are more suitable for environmental reasons, the higher capital and (short-term) running costs mean that they cannot compete without government intervention. However, such cost calculations take no account of the longer term. In the long run, landfill of hazardous materials may impose a larger financial burden than other methods because of the high cost of ensuring that the site remains secure for the time it takes for the waste to be rendered harmless.

Alternate Fuels – Solid Fuels

Solid fuels are those fuels that are solid under ambient conditions and remain solid under mild heating. Thus, examples of solid fuels from biofuel feedstocks include wood and wood-derived charcoal and dried dung, particularly cow dung.

Compared to gaseous fuels and liquid fuels, solid fuels are often cheaper, easier to extract, more stable to transport, and in many places are more readily available. Coal, in particular, is utilized in the generation of electricity because it is less expensive and more powerful than its gaseous or liquid fuel counterparts. However, solid fuels are also heavier to transport, require more destructive methods to extract/burn, and often have higher carbon, nitrate, and sulphate emissions. With the exception of sustainable wood/biomass, solid fuel (such as peat or coal) is typically considered to be non-renewable because it requires thousands of years to form.

Alternative Energy

Alternative energy is a term for any nontraditional energy form, source, or technology differing from the current popular forms, sources, or technologies. Currently, the term alternative energy is generally used in the context of an alternative to energy deriving from the widely-used fossil fuels and thus includes energy derived from such environmentally preferred sources as biomass, geothermal, ocean, solar, tidal action, water power, wave action, and wind power. Many definitions of alternative energy use this term interchangeably with renewable energy.

The term alternative energy is also used for energy derived from sources and technologies that do not involve the depletion of natural resources (such as fossil fuel sources) or significant harm to the environment. As such, the term alternate energy is used synonymously with the terms renewable energy and green energy or green power. The three terms have also been delineated differently even though, by most definitions, there is substantial overlap between energy forms, sources, and technologies that fit into these three categories, and alternative energy often is applied to energy without undesirable environmental consequences or with lessened environmental impact. Renewable energy generally refers most specifically to energy derived from sustainable natural resources that are constantly replenished within a relatively short time frame (such as deriving from such renewable natural resources).

Amine Washing

Amine washing (more correctly olamine washing) of a gas stream involves the chemical reaction of the amine with any acid gases with the liberation of an appreciable amount of heat, and it is necessary to compensate for the absorption of heat. Amine derivatives such as ethanolamine (monoethanolamine, MEA), diethanolamine (DEA), triethanolamine (TEA), methyldiethanolamine (MDEA), di-isopropanolamine (DIPA), and diglycolamine (DGA) have

been used in commercial applications (Table A-19). Amine washing is the primary process for sweetening sour natural gas and is quite similar to the processes of glycol dehydration and removal of natural gas liquids by absorption.

The primary process for sweetening sour natural gas is quite similar to the processes of glycol dehydration and removal of natural gas liquids by absorption. In this case, however, amine (olamine) solutions are used to remove the hydrogen sulfide (the amine process).

Table A-19 Amines (olamines) used for gas processing.

Olamine	Formula
Ethanolamine (monoethanolamine) (MEA)	$\text{HOC}_2\text{H}_4\text{NH}_2$
Diethanolamine (DEA)	$(\text{HOC}_2\text{H}_4)_2\text{NH}$
Triethanolamine (TEA)	$(\text{HOC}_2\text{H}_4)_3\text{N}$
Diglycolamine (hydroxyethanolamine) (DGA)	$\text{H}(\text{OC}_2\text{H}_4)_2\text{NH}_2$
Diisopropanolamine (DIPA)	$(\text{HOC}_3\text{H}_7)_2\text{NH}$
Methyldiethanolamine (MDEA)	$(\text{HOC}_2\text{H}_4)_2\text{NCH}_3$

In the process, the sour gas is run through a tower, which contains the olamine solution. There are two principal amine solutions used, monoethanolamine (MEA) and diethanolamine (DEA). Either of these compounds, in liquid form, will absorb sulfur compounds from natural gas as it passes through. The effluent gas is virtually free of sulfur compounds, and thus loses its sour gas status. Like the process for the extraction of natural gas liquids and glycol dehydration, the amine solution used can be regenerated for reuse.

As currently practiced, acid gas removal processes involve the selective absorption of the contaminants into a liquid, such as an olamine (Table A-19), which is passed countercurrent to the gas. Then, the absorbent is stripped of the gas components (regeneration) and recycled to the absorber. The process design will vary and, in practice, may employ multiple absorption columns and multiple regeneration columns.

Liquid absorption processes (which usually employ temperatures below 50°C (120°F) are classified either as *physical solvent processes* or *chemical solvent processes*. The former processes employ an organic solvent, and absorption is enhanced by low temperatures, or high pressure, or both. Regeneration of the solvent is often accomplished readily. In chemical solvent processes, absorption of the acid gases is achieved mainly by use of alkaline solutions such as amines or carbonates. Regeneration (desorption) can be achieved by the use of reduced pressure and/or high temperature, whereby the acid gases are stripped from the solvent.

Regeneration of the solution leads to near complete desorption of carbon dioxide and hydrogen sulfide. A comparison between monoethanolamine, diethanolamine, and diisopropanolamine shows that monoethanolamine is the cheapest of the three but shows the highest heat of reaction and corrosion; the reverse is true for diisopropanolamine.

The processes using ethanolamine and potassium phosphate are now widely used. The ethanolamine process, known as the *Girbotol* process, removes acid gases (hydrogen sulfide, and carbon dioxide) from liquid hydrocarbons as well as from natural and from refinery gases. The Girbotol process uses an aqueous solution of ethanolamine ($\text{H}_2\text{NCH}_2\text{CH}_2\text{OH}$) that reacts with hydrogen sulfide at low temperatures and releases hydrogen sulfide at high temperatures. The ethanolamine solution fills a tower called an absorber through which the sour gas is bubbled. Purified gas leaves the top of the tower, and the ethanolamine solution leaves the bottom of the tower with the absorbed acid gases. The ethanolamine solution enters a reactivator tower where heat drives the acid gases from the solution. Ethanolamine solution, restored to its original condition, leaves the bottom of the reactivator tower to go to the top of the absorber tower, and acid gases are released from the top of the reactivator.

The chemistry can be represented by simple equations for low partial pressures of the acid gases:

At high acid gas partial pressure, the reactions will lead to the formation of other products:

The reaction is extremely fast, the absorption of hydrogen sulfide being limited only by mass transfer; this is not so for carbon dioxide.

See also: Gas Cleaning, Gas Processing, Gas Treating.

Ammonia

Ammonia is a valuable chemical that is often produced from renewable sources (biomass) that contain nitrogen. It is recoverable from both the liquid and gas streams and can be readily separated from the liquid, by an ammonia still. The fixed salts must be treated with lime or caustic in a lime leg. The gaseous ammonia may be absorbed with sulfuric acid to produce ammonium sulfate, processed to anhydrous ammonia, or destroyed by combustion.

The standard procedure for the manufacture of ammonium sulfate from a gas stream involves several steps. The gas is first cooled to approximately 32°C (90°F) in an appropriate condensation system. Any tar, which is a very troublesome contaminant of ammonium sulfate (and vice versa), condenses and, in addition, much of the water containing approximately 25% of the ammonia (NH₃), primarily as ammonium (NH₄⁺) salts, also condenses. This water is rendered basic (lime treatment), thereby converting the ammonium ion to ammonia, which is recovered by being stripped off in a lime still and placed back in the coal gas stream. The coal gas stream is heated to above its dew point (approximately 65°C; 150°F), and the ammonia is adsorbed in 5 to 10% sulfuric acid solution contained in a lead-lined saturator at a temperature of 50 to 60°C (120 to 140°F); ammonium sulfate crystals precipitate from the sulfuric acid solution.

See also: Petrochemicals.

Anaerobic Digestion

Anaerobic digestion is the decomposition of biological wastes by microorganisms, usually under wet conditions, in the absence of air (oxygen), to produce a gas comprising mostly methane and carbon dioxide.

Anaerobic digestion of animal waste is the primary cause of odors, solids buildup and many diseases in swine, dairy, and poultry facilities, processing plants, municipal waste systems, and septic systems. Animal waste concentrated in pits under slatted floors or collected in holding tanks or lagoons has the natural tendency to involve an anaerobic process. Anaerobic digestion occurs when the anaerobic microbes are dominant over the aerobic microbes. Anaerobic microbes will naturally become dominant in pits or lagoons because of the lack of oxygen in solutions containing heavy concentrations of animal waste, which results in a high biological oxygen demand (BOD). These microbes feed on the animal waste at the bottom of the pits and lagoons. As they digest waste, large amounts of toxic gases are released due to the digestion processes common to the anaerobic microbes.

The anaerobic digestion of animal waste can be changed to aerobic digestion by proper applications of beneficial aerobic microbes in a highly concentrated form. If aerobic microbes are introduced into an environment that is lacking oxygen, they will begin to build oxygen into this environment as long as they survive and reproduce. Aerobes have the ability to do this in a liquid media or in the soil as long as there is an adequate moisture and food source for them to feed on and reproduce. The process is a multi-stage biological treatment process whereby bacteria, in the absence of oxygen, decompose organic matter to carbon dioxide, methane, and water (Table A-20).

Table A-20 Schematic of the anaerobic digestion process.

Feedstock	Products	Products	Products
Carbohydrates	Sugars	Carbon acids	Methane
Fats	Fatty acids	Alcohols	Carbon dioxide
Proteins	Amino acids	Hydrogen	
		Carbon dioxide	
		Ammonia	

In this way, the waste sludge is stabilized and the obnoxious odor is removed. The process can, however, be described adequately and simply as occurring in two stages, involving two different types of bacteria. The process occurs in the absence of air, the decomposition in this case is caused not by heat but by bacterial action. In the first stage, the organic material present in the feed sludge is converted into organic acids (also called volatile fatty acids) by acid forming bacteria. In the second stage, these organic acids serve as the substrate (food) for the strictly anaerobic methane-producing bacteria, which converts the acids into methane and carbon dioxide.

Any organic substance can become subject to anaerobic digestion so long as there are warm, wet, and airless conditions. For example, marsh gas is a product of the anaerobic digestion of vegetation at the bottom of ponds; this gas rises to the surface and bubbles, and the gas is also combustible. With the aid of human intervention, there are two products of this process, biogas and landfill gas. The chemical processes behind the production of these gases are complex. The end result of the process is a well-established sludge in which 40 to 60% of the volatile solids are destroyed. Finally, a combustible gas is produced consisting of 60 to 75% v/v methane and the remainder largely being carbon dioxide. (Table A-21).

Table A-21 Summary of most common chemical reactions in the anaerobic digestion process.

Substrate	Biochemical Reactions
Hydrogen and carbon dioxide	$4\text{H}_2 + \text{CO}_2 \rightarrow \text{CH}_4 + 2\text{H}_2\text{O}$
Carbon monoxide	$4\text{CO} + 2\text{H}_2\text{O} \rightarrow \text{CH}_4 + 3\text{CO}_2$
Alcohols	$4\text{CH}_3\text{OH} \rightarrow 3\text{CH}_4 + \text{CO}_2 + 2\text{H}_2\text{O}$ $\text{CH}_3\text{OH} + \text{H}_2 \rightarrow \text{CH}_4 + \text{H}_2\text{O}$ $4\text{HCOO}^- + 2\text{H}^+ \rightarrow \text{CH}_4 + 2\text{H}_2\text{O}$
Monosaccharides	$\text{C}_6\text{H}_{12}\text{O}_6 + 2\text{H}_2\text{O} \rightarrow 2\text{H}_2 + \text{butyrate} + 2\text{HCO}_3^- + 3\text{H}^+$ $\text{C}_6\text{H}_{12}\text{O}_6 + 4\text{H}_2\text{O} \rightarrow 4\text{H}_2 + 2 \text{acetate} + 2\text{HCO}_3^- + 4\text{H}^+$
Organic Acids	$\text{Butyrate} + 2\text{H}_2\text{O} \rightarrow 2\text{H}_2 + 2 \text{acetate} + \text{H}^+$ $\text{Propionate} + 3\text{H}_2\text{O} \rightarrow 3\text{H}_2 + \text{acetate} + \text{HCO}_3^- + \text{H}^+$ $\text{HCOO}^- + 3\text{H}_2 + \text{H}^+ \rightarrow \text{CH}_4 + 2\text{H}_2\text{O}$ $\text{CH}_3\text{COO}^- + \text{H}_2\text{O} \rightarrow \text{CH}_4 + \text{HCO}_3^-$ $4\text{CH}_2\text{NH}_2 + 2\text{H}_2\text{O} + 4\text{H}^+ \rightarrow 3\text{CH}_4 + \text{CO}_2 + 4\text{NH}_4^+$
Methanogenic substances	$2(\text{CH}_3)_2\text{NH} + 2\text{H}_2\text{O} + 2\text{H}^+ \rightarrow 3\text{CH}_4 + \text{CO}_2 + 2\text{NH}_4^+$ $4(\text{CH}_3)_3\text{N} + 6\text{H}_2\text{O} + 4\text{H}^+ \rightarrow 9\text{CH}_4 + 3\text{CO}_2 + 4\text{NH}_4^+$ $2\text{CH}_3\text{CH}_2\text{-N}(\text{CH}_3)_2 + 2\text{H}_2\text{O} \rightarrow 3\text{CH}_4 + \text{CO}_2 + 2\text{CH}_3\text{CH}_2\text{NH}_2$ $4\text{H}_2 + \text{HCO}_3^- + \text{H}^+ \rightarrow \text{CH}_4 + 3\text{H}_2\text{O}$ $4\text{H}_2 + 2\text{HCO}_3^- + \text{H}^+ \rightarrow \text{acetate} + 4\text{H}_2\text{O}$
Sulfate	$4\text{H}_2 + \text{SO}_4^{2-} \rightarrow \text{HS}^- + 3\text{H}_2\text{O} + \text{OH}^-$

Thus, simplified examples of the chemistry of anaerobic digestion process are as follows:

Carbohydrates $\rightarrow$ sugars $\rightarrow$ acids, alcohols $\rightarrow$ acetic acid, carbon dioxide, hydrogen

Fats → fatty acids → acids, alcohols → acetic acid, carbon dioxide, hydrogen

Protein → amino acids → ammonia, carbon dioxide, hydrogen

Organic acids formed in the first stage of the waste treatment process are converted to methane at the same rate at which they are formed. If not, they accumulate and ultimately lower the pH, leading to inhibition of the second stage of the digestion process and digester failure. Temperature must be maintained within certain ranges – heating increases the activity of the anaerobic bacteria, reducing the required digestion time. A pH of 7.0 to 7.5 is recommended to encourage the methane-producing stage.

The organic content of the sludge is significantly reduced by conversion into gaseous end-products; the obnoxious odor of the sludge is removed, and the final digested sludge has a characteristic tarry odor; fats and greases are broken down by the process. The liquid fraction (supernatant) contains increased levels of ammonia as a result of the breakdown of organic nitrogen (proteins). This makes the digested sludge liquor potentially suitable for agricultural use; the biogas that is formed is a mixture of carbon dioxide (CO₂) and methane (CH₄) that can be used for digester heating or to generate power.

The slow rate of bacterial growth usually requires long periods of time for start-up and limits the flexibility of the process to adjust to changing feed loads, temperatures, and other environmental conditions. In addition, the process is prone to upsets if not regularly monitored and if corrective action is not taken in time.

Anaerobic Digestion – Gas Production

A typical gas system for the production of gas by anaerobic digestion comprises the digester cover, pressure and vacuum relief devices, water trap, flame trap, pressure regulator, gas meter, check valve, pressure gauges, waste gas burner, and a gas holder. The continuous stirred tank reactor (CSTR) is an example of a type of anaerobic digester.

The digester is covered to contain odors, maintain temperature, keep air out, and collect the gas. Fixed covers are more usual than floating covers. During normal operation, there is a space for gas collection between the cover and the liquid surface of the digester contents. The cover of a digester has certain unique features that the operating staff must be aware of, for example, how the variation in pressure and the level inside the digester may affect the cover. The biggest danger associated with the operation of fixed cover digesters occurs when the pressure relief device mounted on top of the digester fails or the sludge overflow line blocks and the liquid level in the digester continues to rise. In such a situation, the excess gas pressure inside the digester can exceed the maximum design pressure and damage the cover or its mountings. Fixed covers can also be damaged by excess negative pressure (vacuum) or if the rate of waste sludge withdrawal exceeds the feed rate or the vacuum relief device fails.

Gas leaving the digester is almost saturated with water vapor. As the gas cools, the water vapor condenses causing problems, which are more severe when digesters are heated. It is essential to remove as much of the moisture as possible before the gas comes into contact with the gas system devices. For this reason, water traps should be located as close to the digester as possible. All piping should be sloped a minimum of 1% toward the water trap, which should be situated at a low point in the gas line.

Flame traps are emergency devices installed in gas lines to prevent flames traveling back up the gas line (flash-back) and reaching the digester. The flame trap generally consists of a box filled with stone or a metal grid. If a flame develops in the gas line, the temperature of the flame is reduced below the ignition point as it passes through the trap and the flame is extinguished. Many anaerobic digestion waste treatment plants have a means of storing excess gas, either in the form of a floating roof on the digester or a separate gasholder.

A mixture of biogas and air can be explosive. Methane gas in concentrations of between 5% and 15% in air by volume is explosive and all piping and equipment must be sealed properly to prevent gas from escaping to the outside. In addition, all electrical installations, including light switches, and torches must be of the explosion-proof type, as the smallest spark could ignite escaped gases.

Animal Waste

Animal wastes, or manure, as a source of biomass has the advantage that it is not competitive with other uses for this material. In the broader senses, animal waste can also include, in addition to animal manure, related animal waste (such as bedding and feed), dead animals, and waste from slaughter and meat processing. All such wastes generally fall in to a sub-class of biomass. Animal waste must of necessity come from confined operations such as dairy farms, cattle feedlots, and slaughter houses as well as meat processing plants.

Animal waste from farms and livestock/poultry and dairy production operations can severely threaten water quality if not managed properly and has the potential to contribute excess nutrients, pathogens, organic matter, solids, and odorous compounds to the environment. This pollution can cause eutrophication of surface waters, degradation of ground water quality, and threats to human health.

Historically, manure generated by livestock has been returned to the soil to improve its tilth and fertility. Recently, the use of animal waste to produce an renewable fuel (biogas) has become of interest. Anaerobic digestion is a renewable solution to livestock waste management that offers economic and environmental benefits.

Anaerobic digestion is a process to decompose organic material in the absence of oxygen. Biogas is produced as a waste product of digestion. In the first stage, the volatile solids in manure are converted into fatty acids by anaerobic bacteria (acid formers). In the second stage, these acids are further converted into biogas by more specialized bacteria (methane formers). With proper planning and design, this anaerobic-digestion process can be managed to convert the waste-stream from a farm into an asset and is, currently, the most appropriate option for farms and small-scale operation. The conversion of animal waste to gas by this process could result in animal husbandry operations being self-sufficient in energy.

Biogas produced in an anaerobic digester typically contains methane (60 to 70% v/v), carbon dioxide (30 to 40% v/v), various toxic gases (including hydrogen sulfide, ammonia, and sulfur-derived mercaptans), and 1 to 2% v/v water vapor.

Annual Removal

The annual removal is the net volume of growing stock trees removed from the inventory during a specified year by harvesting, cultural operations, such as, timber stand improvement, land clearing, and removal of trees killed or damaged by natural causes (natural losses), e.g. fire, wind blow, insects and diseases.

An example is clipping (i.e., harvesting aboveground plant biomass) which is common in agriculture and for bioenergy production.

Forest ecosystems contain large amounts of nutrients in woody biomass that may exist either as standing material, on the soil surface, or within the soil profile. Logs removed during timber harvesting remove considerable amounts of nutrients, and the disturbance caused by the process may sometime later, if not immediately, affect the amount of nutrients left on the site due to increased soil erosion, mineralization, and leaching. Thus, intensive harvesting, which removes a greater proportion of the forest biomass than conventional harvesting and the associated nutrients, may cause a decline in forest productivity.

Separately, warming and clipping alter soil and plant properties in either similar or contrasting fashions. For example, in grassland areas, both warming and clipping were observed to increase soil temperature and decrease soil moisture. In contrast, warming increased net primary productivity and plant carbon input to soil, but clipping reduced both. Moreover, warming led to an extended growing season length, while clipping caused compensatory root growth and stimulated exudation of carbon. The interactive effects of warming and clipping on these soil and plant properties rely on the mechanisms governing each single factor and the degree to which these factors interact. The responses of soil microbial communities to two or more factors are even less predictable than those of soil and plant properties, owing to their extremely high diversity.

Apparent Density

The apparent density (*bulk density*) is the weight per unit volume of a material, such as coal, which includes the voids that exist in the tested material (Table A-22).

Table A-22 Measurement of the apparent density of materials.

Method	Use	Test
A	For fine granules and powders that can be poured through a small funnel.	Test is performed by pouring the material through a funnel into a cylinder of known volume. The apparent density is calculated by dividing the weight of the material in the cylinder by the volume of the cylinder.
B	For coarse, granular materials that either cannot be poured or that pour with difficulty through the funnel from Method A.	Test is performed by pouring the material through a funnel into a cylinder of known volume. The apparent density is calculated by dividing the weight of the material in the cylinder by the volume of the cylinder.
C	For coarse flakes, chips, cut fibers, or strands that cannot be tested with Methods A or B.	Test is performed by pouring the material into a graduated cylinder and allowing a 2300-g plunger to pack the material for 1 minute. The apparent density is taken as the mass of the material divided by the settled volume.

The bulk factor is the ratio of the density of a material after molding to the density of the raw material and provides a measure of the volume change that can be expected during processing.

The apparent density is not an intrinsic property of a material; it can change depending on how the material is handled. For example, a powder poured in to a cylinder will have a particular bulk density; if the cylinder is disturbed, the powder particles will move and usually settle closer together, resulting in a higher bulk density. For this reason, the bulk density of powders is usually reported both as “freely settled” and “tapped” density (where the tapped density refers to the bulk density of the powder after a specified compaction process, usually involving vibration of the container).

Aquaculture

Aquaculture is the raising of fish and other aquatic animals in a controlled environment – it is the farming of fish, shellfish, and other freshwater or marine (saltwater) creatures. Using geothermal water in aquaculture helps keep water temperatures consistent, which increases survival rates and makes the creatures grow faster. Low-temperature geothermal resources that are not hot enough to produce electricity are useful to fish farmers. Animals grown in water of the proper temperature grow faster and larger than those in cold water or water with fluctuating temperatures. They are also more resistant to disease and die less frequently.

Fish farmers with access to geothermal water can use it to regulate the temperatures of their fish ponds. Though the mechanism to accomplish this can be complicated, basically what happens is that the fish farmer opens valves to allow geothermal water to flow into the fish ponds until they reach the desired temperature. The valves are then closed to prevent the water from getting too hot. The mechanism is similar to adding hot water to a bathtub to bring the temperature to the desired level. Water flow can be adjusted throughout the year to account for air temperatures. Most ponds contain some mechanism to circulate the water and keep it all at an even temperature. Aquaculture operations usually have several ponds, which are kept small enough to be heated or cooled easily.

The main species of fish that are raised in geothermal waters are catfish, bass, trout, tilapia, sturgeon, giant freshwater prawns, alligators, snails, coral, and tropical fish. The warmth of geothermal water makes it possible to raise tropical marine (saltwater) species in cold, land-locked places such as Idaho.

Some creatures have a range of temperatures in which they thrive. For example, catfish and shrimp grow at approximately 50% of the optimum rate at temperatures between 20 and 26°C (68 and 79°F) and grow fastest at approximately 32°C (90°F), but they decline at temperatures higher than that. Trout thrive at around 15°C (60°F) but dislike lower or higher temperatures.

Like other direct uses of geothermal water, aquaculture allows an area to make use of groundwater that may not be hot enough to generate electricity, but is still hot enough to be useful as hot water. Arizona, for example, has a great deal of geothermal water that is under 150°C (300°F), which cannot generate electricity, but is very useful in aquaculture.

The fish grown in geothermal fisheries are healthier and stronger than fish grown in unheated fish ponds. Fish farmers can regulate temperature throughout the year to make sure the fish grow to a consistent size year-round. However, fish farmers must be careful to regulate water temperature. The water in and near the pipes bringing in the hot groundwater can get very hot, creating pockets that are too hot for fish. For aquaculture to work well, there must be a source of cool water in addition to the hot water. Some geothermal fisheries collect geothermal water in holding ponds and let it cool in order to regulate pond temperatures. If the water does not circulate evenly, there can also be cold spots. This can make the fish crowd into areas where the temperature is at the right level. The hot pipes also can be dangerous to human workers who must wade into the pools for repairs, feeding, and harvesting.

For the most part, using hot groundwater to heat fish ponds is good for the environment. A farm that uses geothermal water is not burning fossil fuels or other sources of heat to regulate water temperature and is therefore not emitting pollutants. Many geothermal aquaculture operations use water that has already been used by geothermal power plants or heating systems. The water has lost most of its heat but is still hot enough to raise the temperature of the fish ponds, so it can be put to a second use before disposal.

Aquaculture itself has both good and bad aspects for the environment. It takes pressure off wild fisheries, many of which have been severely overfished. In some areas, however, it contributes to pollution of the water.

Economically, using geothermal energy to heat water for aquaculture can have many benefits. Places that use water that has already been used for heating or electricity generation can heat their fish ponds essentially for no cost. They can also enjoy the economic benefit of selling the fish or prawns that they produce. Fish grown in geothermally heated water grow faster than fish in unheated water, so some fish farmers can grow extra fish crops for sale. Heated water makes it possible to grow fish in winter when it ordinarily would not be possible. Selling tropical fish for the pet store market can be quite profitable. Developing nations can export their fish produce for good prices, bringing foreign capital into the country.

Aquasphere

The Earth is a unique planet insofar as there is an abundance of water that is necessary to sustaining life on the Earth, and helps tie together the atmosphere, the land (the geosphere), and the oceans and rivers (the aquasphere) into an integrated system. Precipitation, evaporation, freezing and melting, and condensation are all part of the hydrological cycle, which is a never-ending global process of water circulation from clouds to land, to the ocean, and back to the clouds. This cycling of water is intimately linked with energy exchanges among the atmosphere, ocean, and land that determine the climate of the Earth and cause much of natural climate variability. The impacts of climate change and variability on the quality of human life occur primarily through changes in the water cycle.

The water systems of the Earth, often referred to as the aquasphere or the hydrosphere, refer to water in various forms: oceans, lakes, streams, snowpack, glaciers, the polar ice caps, and water under the ground (groundwater). An important aspect of the water systems is an aquifer which is a water-bearing (water-rich) subsurface formation (a subsurface zone) that yields water to wells. An aquifer may be porous rock, unconsolidated gravel, fractured rock, or

cavernous limestone. Aquifers are important reservoirs storing large amounts of water which, in theory, should be relatively free from evaporation loss or pollution. However, in practice, this is not always the case.

The aquasphere consists of a variety of non-oceanic water systems (Table A-23) that are essential to life, and all are interrelated, and the many interactions between the systems of the Earth are complex, and they are occurring constantly and simultaneously although the effects are not always obvious.

Table A-23 Sources of non-oceanic water and water systems.

Source	Description
Surface water	Water in a river, lake or fresh water wetland; the water is naturally replenished by precipitation and naturally lost through discharge to the oceans, evaporation, evapotranspiration, and groundwater recharge.
Groundwater	Fresh water located in the subsurface pore space of soil and rocks; also water that is flowing within aquifers below the water table.
Aquifer water	Fresh water in a layer of sediment or rock that is highly permeable; usually water in a layer of sand and gravel that have high permeability.
Unconfined aquifer	An aquifer that is overlaid by permeable earth materials and which is recharged by water seeping down from above in the form of rainfall and snow melt.
Confined aquifer	An aquifer which is sandwiched between two impermeable layers of rock or sediments and are recharged only in those areas where the aquifer intersects the land surface.

The oceans play a key role in the water cycle insofar as the oceans hold 97% v/v of the total water on the Earth and 78% v/v of the global precipitation occurs over the oceans, and it is the source of 86% v/v of global evaporation. Besides affecting the amount of atmospheric water vapor and hence rainfall, evaporation from the sea surface is important in the movement of heat in the climate system. Water evaporates from the surface of the ocean, mostly in warm, cloud-free subtropical seas. This continuing event cools the surface of the ocean, and the large amount of heat absorbed the ocean partially buffers the greenhouse effect from increasing carbon dioxide and other gases. Water vapor carried by the atmosphere condenses as clouds and falls as rain, mostly in the intertropical convergence zone (ITCZ), far from where it evaporated. Condensing water vapor releases latent heat which drives much of the atmospheric circulation in the tropics. This latent heat release is an important part of the heat balance of the Earth, and it couples the energy and water cycles of the Earth.

The intertropical convergence zone, known by sailors as the doldrums or the calms because of the monotonous, windless weather, is the area where the northeast and southeast trade winds converge. The zone encircles Earth near the thermal equator, although the specific position of the zone can vary on a seasonal basis. When the zone lies near to the geographic equator, it is referred to as the near-equatorial trough. When the intertropical convergence zone is drawn into and merges with a monsoonal circulation, the zone is sometimes referred to as a monsoon, a usage that is more common in Australia and parts of Asia.

The major physical components of the global water cycle include the evaporation from the ocean and land surfaces, the transport of water vapor by the atmosphere, precipitation onto the ocean and land surfaces, the net atmospheric transport of water from land areas to ocean, and the return flow of fresh water from the land back into the ocean. The additional components of oceanic water transport are few, including the mixing of fresh water through the oceanic boundary layer, transport by ocean currents, and sea ice processes.

On land, the situation is more complex, and includes the deposition of rain and snow on land; water flow in runoff; infiltration of water into the soil and groundwater; storage of water in soil, lakes and streams, and groundwater; polar and glacial ice; and use of water in vegetation and human activities. Processes labeled include precipitation, condensation, evaporation, evapotranspiration (from tree into atmosphere), radiative exchange, surface runoff, ground water and stream flow, infiltration, percolation, and soil moisture. Furthermore, in the water systems (particularly in the lakes) the term eutrophication becomes important. Eutrophication is the deterioration of the esthetic and lifesupporting qualities of lakes and estuaries, caused by excessive fertilization from effluents high in phosphorus, nitrogen, and organic growth substances. Algae and aquatic plants become excessive, and when they decompose, a sequence of objectional features arises.

Water for human consumption (and, in many cases as on farms for animal consumption) from such lakes must be filtered and treated. Diversions of sewage, better utilization of manure, erosion control, improved sewage treatment, and harvesting of the surplus aquatic crops alleviate the symptoms.

There are some extremely dramatic examples of Earth systems interacting, such as volcanic eruptions and ocean tsunamis, but there are also slow, nearly undetectable changes that alter ocean chemistry, the content of the atmosphere, and the microbial biodiversity in soil. Each part of the Earth, from inner core to the top of the atmosphere, has a role in making Earth suitable for the existence of billions of lifeforms ($1 \text{ billion} = 1 \times 10^9$). Within the aquasphere, the phenomenon known as (i) precipitation, (ii) evaporation, (iii) freezing, (iv) melting, and (v) condensation are part of the hydrological cycle – also known as the water cycle – which is a continuous global process of water circulation from clouds to land, to the ocean, and back to the clouds.

The water cycle describes the means by which water evaporates from the surface of the Earth, rises into the atmosphere, cools, condenses to form clouds, and falls again to the surface as precipitation. This system of the cycling of water is intimately linked with energy exchanges among the atmosphere, the ocean, and land that determine the climate of the Earth and cause much of natural climate variability. For example, approximately 75% of the energy (or heat) in the global atmosphere is transferred through the evaporation of water from the surface of the Earth. On land, water evaporates from the ground, mainly from soils, plants (through transpiration), lakes, and streams. In fact, approximately 15% v/v of the water entering the atmosphere is from evaporation from the land surfaces and evapotranspiration from plants which (i) cools the surface of the Earth, (ii) cools the lower atmosphere, and (iii) provides water to the atmosphere to form clouds.

The major physical components of the global water cycle include (i) the evaporation from the ocean and land surfaces, (ii) the transport of water vapor by the atmosphere and precipitation onto the ocean and land surfaces, (iii) the net atmospheric transport of water from land areas to ocean, and (iv) the return flow of fresh water from the land back into the ocean. The additional components of oceanic water transport are few, including the mixing of fresh water through the oceanic boundary layer, transport by ocean currents, and sea ice processes.

Water pollution has become a widespread phenomenon and has been known for centuries, particularly the pollution of rivers and groundwater. By way of example, in ancient time up to the early part of the 20th century, many cities deposited waste into the nearby river or even into the ocean. It is only very recently (because of serious concerns for the condition of the environment) that an understanding of the behavior and fate of chemicals, which are discharged to the aquatic environment as a result of these activities, is essential to the control of water pollution. In rivers, the basic physical movement of pollutant molecules is the result of advection, but superimposed upon this are the effects of dispersion and mixing with tributaries and other discharges. Some of the chemicals discharged are relatively inert, so their concentration changes only due to advection, dispersion, and mixing. However, many substances are not conservative in their behavior and undergo changes due to chemical or biochemical processes, such as oxidation.

In addition, there are many indications that the chemical materials in the aquasphere (also called, when referring to the sea, the marine aquasphere) are subject to intense chemical transformations and physical recycling processes imply that a total carbon approach is not sufficient to resolve the numerous processes occurring. The transport of anthropogenically produced or distributed compounds such as crude oil hydrocarbon derivatives and halogenated hydrocarbon derivatives, including the polychlorobiphenyl derivatives the DDT family, and the Freon derivatives and the chemistry of these chemicals in water is not fully understood.

The effects of a chemical released into the marine environment (or any part of the aquasphere) depends on several factors such as (i) the toxicity of the chemical, (ii) the quantity of the chemical, (iii) the resulting concentration of the chemical in the water column, (iv) the length of time that floral and faunal organisms are exposed to that concentration, and (v) the level of tolerance of the organisms, which varies greatly among different species and during the life cycle of the organism. Even if the concentration of the chemical is below what would be considered as the lethal concentration, a sub-lethal concentration of an chemical can still lead to a long-term impact within the aqueous marine environment. For example, chemically-induced stress can reduce the overall ability of an organism to reproduce, grow, feed, or otherwise function normally within a few generations. In addition, the characteristics of some chemicals can result in an accumulation of the chemical within an organism (*bio-accumulation*) and the organism may be particularly vulnerable to this problem. Furthermore, subsequent bio-magnification may also occur if the chemical (or a toxic product produced by one or more transformation reactions) can be passed on, following the food chain up to higher flora or fauna.

In terms of a chemical spill into the environment, the complex processes of transformation start developing almost as soon as the chemical contacts the land (or the water) although the progress, duration, and result of the transformations depend on the properties and composition of the chemical, parameters of the spill, and environmental conditions. The major operative processes are (i) physical transport, (ii) dissolution, (iii) emulsification, (iv) oxidation, (v) sedimentation, (vi) microbial degradation, (vii) aggregation, and (viii) self-purification.

In terms of *physical transport*, the distribution of oil spilled on the sea surface occurs under the influence of gravitational forces and is controlled by the viscosity of the (liquid) chemical as well as the surface tension of the water. In addition, during the first several days after a spill of a liquid chemical or a mixture of liquid chemicals, a part of spilled chemical may be lost through evaporation and any water-soluble constituents disappear into the water. The portion of the chemical mixture that remains is the more viscous fraction. Further changes take place under the combined impact of meteorological and hydrological factors.

Many organic chemicals are not *soluble* in water, although some constituents may be water-soluble to a certain degree, especially low-molecular-weight aliphatic and aromatic hydrocarbon derivatives. Polar compounds formed as a result of oxidation of some oil fractions in the marine environment also dissolve in seawater. Compared to evaporation process, the dissolution of organic chemicals in water is a slow process. However, the *emulsification* of a chemical (or chemicals) in the aquasphere does occur but depends predominantly on the presence of organic functional groups in the spilled material which can increase with time due to oxidation. The rate of emulsification process can be decreased by use of emulsifiers – surface-active chemicals with strong hydrophilic properties used to eliminate oil spills – which help to stabilize oil emulsions and promote dispersing oil to form microscopic (invisible) droplets that accelerates the decomposition of the chemicals in the water.

Oxidation is a complex process that can ultimately results in the destruction of the crude oil constituents. The final products of oxidation (such as hydroperoxide derivatives, phenol derivatives, carboxylic acid derivatives, ketone derivatives, and aldehyde derivatives) usually have increased water solubility. This can result in the apparent disappearance of the chemicals from the surface of the water. This is due to the incorporation of oxygen-containing functional groups into the chemicals which results in a change in density with an increase in the ability of the transformed chemicals to become miscible (or emulsify) and sink to various depths of the water system as these changes intensify. These chemical changes also result in an increase in the viscosity of the chemicals which promotes the formation of solid oil aggregates. The reactions of photo-oxidation, photolysis in particular, also initiates transformation of the more complex (polar) chemicals.

As these processes occur, some of the chemicals are adsorbed on any to suspended material and deposited on the floor of the water system (sedimentation), the rate of which is dependent upon the ocean depth – in deeper areas remote from the shore, sedimentation of oil (except for the heavy fractions) is a slow process. Simultaneously, the process of *biosedimentation* occurs – in this process, plankton and other organisms absorb the emulsified chemical – and the transformed chemical is sent to the bottom of the water system as sediment with the metabolites of the plankton and other organisms. However, this situation radically changes when the suspended chemical(s) oil reaches the bottom – the decomposition rate of the chemical ceases abruptly especially under the prevailing anaerobic conditions, and any chemicals that have accumulated inside the sediments can be preserved for many months and even years. These products can be swept to the edge of the water system (the river bank, the lake shore, or the beach in the case of a spill into an ocean) by turbulent condition at some later time.

Self-purification is a result of the processes previously described above in which a chemical in the environment rapidly loses the original properties and disintegrates into various products. These products may have different a chemical composition and structure to the original chemical and exist in different migrational forms, and they undergo chemical transformations that slow after reaching thermodynamic equilibrium with the environmental parameters. Eventually, the original and intermediate compounds disappear, and carbon dioxide and water form. This form of self-purification inevitably happens in water ecosystems if the amount of toxic chemicals spilled into the system does not exceed acceptable limits.

While acid-base reactions are not the only chemical reactions important in aquatic systems, they do present a valuable starting point for understanding the basic concepts of chemical equilibria in such systems. Carbon dioxide (CO_2), a gaseous inorganic chemical substance of vital importance to a variety of environmental processes, including growth and decomposition of biological systems, climate regulation, and mineral weathering, has acid-base properties that are critical to an understanding of its chemical behavior in the environment. The phenomenon of acid rain is another example of the importance of acid-base equilibria in natural aquatic systems.

Furthermore, the almost unique physical and chemical properties of water as a solvent are of fundamental concern to aquatic chemical processes. For example, in the liquid state, water has unusually high boiling point and melting point temperatures compared to its hydride analogues from the periodic table of the elements (Table 8.10) such as ammonia (NH_3), hydrogen fluoride (HF), and hydrogen sulfide (H_2S). Hydrogen bonding between water molecules means that there are strong intermolecular forces making it relatively difficult to melt or vaporize.

In addition, pure water has a maximum density at 4°C (39°F), higher in temperature than its freezing point (0°C , 32°F), and that ice is substantially less dense than liquid water, and is important (and fortunate) in several contexts. Thus, as water in a lake is cooled at its surface by loss of heat to the atmosphere, the ice structures formed will float. Furthermore, a dynamically stable water layer near 4°C (39°F), will tend to accumulate at the bottom of the lake, and the overlying, less dense water able to continue cooling down to the freezing point. This means that ice will eventually coalesce at the surface, forming an insulating layer that greatly reduces the rate of freezing of the underlying water. This situation is obviously important for plants and animals that inhabit lake waters.

In addition, the presence of salt components means that the temperature of maximum density for seawater is shifted to lower temperatures: in fact, the density of seawater continues to increase right down to the freezing point. The high concentration of electrolytes in seawater assist in breaking up the open, hydrogen-bonded ice-like structure of water near its freezing point. Because the salt components tend to be excluded from the ice formed by freezing seawater, sea ice is relatively fresh and still floats on water. Much of the salt it contains is not truly part of the ice structure but contained in brines that are physically entrained by small pockets and fissures in the ice.

The dielectric constant of water (78.2 at 25°C , 77°F) is high compared to most liquids. Of the common liquids, few have comparable values at this temperature, e.g., hydrogen cyanide (HCN, 106.8), hydrogen fluoride (HF, 83.6), and sulfuric acid (H_2SO_4 , 101). By contrast, most non-polar liquids have dielectric constants on the order of 2. The high dielectric constant helps liquid water to solvate ions, making it a good solvent for ionic substances, and arises because of the polar nature of the water molecule and the tetrahedrally-coordinated structure in the liquid phase.

In many electrolyte solutions of interest, the presence of ions can alter the nature of the water structure. Ions tend to orient water molecules that are near to them. For example, cations attract the negative oxygen end of the water dipole toward them. This reorientation tends to disrupt the ice-like structure further away. This can be seen by comparing the entropy change on transferring ions from the gas phase to water with a similar species that does not form ions.

As an example of chemical transformation that can occur in a water system, the chemistry of methyl iodide (which is thermodynamically unstable in seawater) is known and its chemical fate is kinetically controlled. The equations showing the fate of methyl iodide are as follows:

In this equation, $\text{X} = \text{Cl}^-, \text{Br}^-, \text{I}^-$

Chloride ion was theoretically predicted to be the most kinetically reactive species, with water second, and other anions of lesser importance. This suggested that methyl iodide in seawater would react predominantly via a nucleophilic substitution reaction with chloride ion to yield methyl chloride. Methyl iodide and the methyl chloride produced by would also react with water, although more slowly, to yield methanol and halide ions. According to these experiments, substantial amounts of methyl chloride should be formed in seawater. Methyl chloride has a long half-life for decomposition by known reactions in seawater. Hence, its presence could be a useful label for some surface-derived water masses. Methyl chloride is in fact found in the atmosphere, where compared to methyl iodide, it is less stable to photo-degradation reactions.

Steroids are a class of biogenic compounds which may serve as an indicator of certain processes transforming matter in seawater and sediments. The steroid hydrocarbon structure (Figure A-2) forms a relatively stable nucleus which may incorporate functional groups such as alcohols (sterol derivatives and stanol derivatives), ketone

derivatives (stanone derivatives) and olefin linkages (sterene derivatives) either in the four ring system or on the side chain originating at C-17.

Figure A-2 The hydrocarbon framework of the steroid system (ring lettering and atom numbering are shown).

These compounds are produced by a wide variety of marine and terrestrial organisms and often have specific species sources. Diagenetic alteration of steroids by geochemical and biochemical processes can lead to the accumulation of transformed products in seawater and sediments.

Within the group of chlorinated compounds, chlorinated ethylene derivatives are the most often detected groundwater pollutants. Tetrachloroethylene (PCE) is the only chlorinated ethylene derivative that resists aerobic biodegradation. Trichloroethylene (TCE), all three isomers of dichloroethylene ($\text{CCl}_2=\text{CH}_2$ and the cis/trans isomers of $\text{CHCl}=\text{CHCl}$), and vinyl chloride ($\text{CH}_2=\text{CHCl}$) are mineralized in aerobic co-metabolic processes by methanotropic or phenol-oxidizing bacteria. Oxygenase derivatives with broad substrate spectra are responsible for the co-metabolic oxidation. Vinyl chloride is furthermore utilized by certain bacteria as carbon and electron source for growth. All chlorinated ethylene derivatives are reductively dechlorinated under anaerobic conditions with possibly ethylene or ethane as harmless end-products.

Tetrachloroethylene ($\text{CCl}_2=\text{CCl}_2$) is dechlorinated to trichloroethylene ($\text{CCl}_2=\text{CHCl}$) in a co-metabolic process by methanogens, sulfate reducers, homoacetogen derivatives, and others. Furthermore, tetrachloroethylene and trichloroethylene serve in several bacteria as terminal electron acceptors in a respiration process. The majority of these isolates dechlorinate tetrachloroethylene and trichloroethylene to cis-1,2-dichloroethene, although they have been isolated from systems where complete dechlorination to ethene occurred.

1,1-Dichloroethylene

Cis-1,2-dichloroethylene

Trans-1,2-dichloroethylene

If chemicals have become subsurface contaminants that threaten important drinking water resources. A strategy to remediate such polluted subsurface environments is with the help of the degradative capacity of bacteria.

Aquatic Organisms

Aquatic organisms can be classified into each varying in the biological characteristics, habitat, and adaptations, but linked within a complex network of ecological roles and relationships.

Microorganisms (algae, bacteria, and fungi) are living catalysts that enable a vast number of chemical processes to occur in water and soil. The living organisms (biota) in an aquatic ecosystem may be classified as either autotrophic or heterotrophic. Autotrophic organisms utilize solar or chemical energy to fix elements from simple, nonliving inorganic material into complex life molecules that compose living organisms. Algae are typical autotrophic aquatic organisms. Generally, carbon dioxide (CO_2), nitrate (NO_3), and phosphate derivatives (PO_4^{3-}) are sources of carbon, nitrogen, and phosphorus, respectively, for autotrophic organisms. Organisms that utilize solar energy to synthesize organic matter from inorganic materials are called producers.

Macrophytes are individual aquatic plants that can be seen by the unaided eye and can be categorized based on where and how they grow. **Rooted macrophytes** are rooted in the riverbed or lake substrate, and are thus restricted to areas where flow is low enough to permit fine sediments to accumulate. Rooted macrophytes may have leaves entirely submerged (under the water), floating on the surface, or emergent above the surface. In turbid water, little light penetrates and photosynthesis is restricted; hence, only plants with floating or emergent leaves can thrive. Rooted macrophytes may extract nutrients from the substrate as well as absorbing them from the water as algae do. Floating aquatic macrophytes are rootless plants that persist only in backwater areas where the flow slackens—otherwise, they are carried downstream. Because their photosynthetic surfaces are above the water surface, these plants can grow in deep, turbid water and places where rooting sites are sparse.

Macrophyte abundance can fluctuate seasonally as a result of scouring of the bottom sediments and washout of plants during heavy rains. For this reason, the number of macrophytes in river channels generally peaks during periods of low flow. Aquatic macrophytes are important in many aquatic systems, especially wetlands, slower moving water in streams and rivers, and in shallower areas of lakes. Aquatic macrophytes add three-dimensional complexity to aquatic habitat, and can provide habitat, refuge, and spawning areas for animals such as aquatic insects and fish, as well as a surface for periphyton growth. As they are primary producers, aquatic macrophytes produce organic matter which can be eaten by some fish; however, most of this plant material is unpalatable to herbivores while it is alive.

Large populations of aquatic macrophytes can have negative effects on aquatic ecosystems and the people that rely on them. In some cases, floating plants are so numerous that they form dense mats covering the water surface. Their buoyant leaf crowns merge above the surface, while the root masses dangle below into the water. The interlocking vegetation mat blocks light penetration down the water column and prevents the growth of other plants. In extreme cases, the underlying water becomes deoxygenated, and floating plants turn into a nuisance by inhibiting the passage of boats and interfering with fishing. Invasive species of macrophytes can be particularly disruptive to natural aquatic ecosystems.

Invertebrates include all animals without a backbone. Invertebrates are far more diverse and abundant than vertebrates, and many groups of invertebrates are found in aquatic systems. Invertebrates living on or in aquatic sediments are termed benthic invertebrates. Benthic invertebrate communities – including measurements of population abundance and diversity – are often used as indicators of aquatic ecosystem health.

Zooplankton are aquatic animals that cannot swim against water currents, typically because they are too small to do so. However, many zooplankton can swim significant distances in fairly still waters. Because they cannot swim against currents, zooplankton are more important in lakes than in running water, as running water usually carries them downstream faster than they can reproduce. However, they can be abundant in large slow flowing rivers. Zooplankton are heterotrophic and are significant sources of energy and nutrients to carnivorous invertebrates and some vertebrates.

Heterotrophic organisms utilize the organic substances produced by autotrophic organisms as energy sources and as the raw materials for the synthesis of their own biomass. Decomposers (or reducers) are a subclass of the heterotrophic organisms and consist of chiefly bacteria and fungi, which ultimately break down material of biological origin to the simple compounds originally fixed by the autotrophic organisms.

Insects are the most diverse group of animals on earth – most insects are terrestrial, while some have life stages that are aquatic (such as dragonflies and mosquitoes). Some insects are entirely aquatic (such as the aquatic beetles). While most aquatic insects live on or near the bottom of waterbodies, though some can swim into the water column. Most aquatic insects have gills and need water with dissolved oxygen, while others, such as mosquito larvae, breathe

through the surface film of still waters. Stream and river insects are crucial in the processing of organic matter. Some scrape biofilm; others shred larger leaves into smaller particles, while still others filter or collect these smaller particles. This chain of processing reduces large organic matter to successively smaller and smaller particles.

Fish display every major feeding type: (i) herbivorous fish feed on periphyton or macrophytes, or may even filter phytoplankton from the water, (ii) carnivorous fish feed on mollusks, worms, insects, zooplankton, and other fish, (iii) omnivorous fish may feed on specific types of prey, or feed indiscriminately on nearly anything they can consume. Due to this diversity in modes of feeding, different fish can occupy different places in a food chain.

As with feeding behavior, some fish occupy specific habitats, while others can be found in a wide variety of lakes and rivers. The distribution of fish can be influenced by a large number of factors, including (i) oxygen concentration, (ii) temperature, (iii) the presence of macrophytes, (iv) the availability of suitable substrate for spawning, and (v) current speed in streams and rivers. Changes in fish habitat (such as reduction of flooding due to damming) can favor some types of fish, and disadvantage others.

Aquatic Plants

Aquatic plants (also known as hydrophytic plants, hydrophytes) are plants that have adapted to living in aquatic environments and are also referred to as hydrophytes or macrophytes to distinguish them from algae and other microphytes. A macrophyte is a plant that grows in or near water and is emergent, submergent, or floating. The three types of aquatic plants are (i) submerged aquatic weeds, submerged plants are rooted in the pond bottom and grow up through the water column, (ii) emergent aquatic weeds, and (iii) free floating aquatic weeds.

Aquatic plants include kelp from the ocean, and freshwater plants such as algae, water hyacinth, and duckweed. Aquatic plants are considered to be a sub-category of biomass and the plants, like wood products, dried vegetation, and crop residues, have the potential to produce biomass fuels.

Aquatic plants have adapted to living in or on aquatic environments and, because living on or under water surface requires numerous special adaptations, aquatic plants can only grow in water or permanently saturated soil. As opposed to typical plant types, aquatic plants do not have a problem in retaining water due to the abundance of water in its environment. This means that the plant has less need to regulate transpiration which requires less energy and increases the possible benefits.

Enhancing the growth rate of these plants by increased nutrient supply, for example, from carbon dioxide in flue gases, or growing suitable plants in conjunction with municipal wastewater treatment facilities, has received some attention. While quantitative data and costs for this resource are limited, full development of the aquatic biomass energy potential is not expected to approach 1% of total US energy requirements.

Algae are tiny aquatic plants have the potential to grow extremely fast in the hot, shallow, saline water found in some lakes in the desert Southwestern United States. Forms of algae thrive on carbon dioxide, and emissions from power plants have been used to feed the plants, which are then used in biofuels.

Aquiclude, Aquitard, Aquifuge

An aquiclude is a water-bearing layer in which both the horizontal and vertical flow components are so small that they can be neglected. The groundwater flow in an aquiclude is assumed to be zero.

Impervious rock in the unsaturated zone may retain water infiltrating from the surface to produce a perched water table that is above the main water table and from which water may be extracted. However, the amounts of water that can be extracted from such a formation are limited and the water is vulnerable to contamination.

An aquitard is a water-bearing layer in which the horizontal flow component is so small with respect to the vertical flow component that it can be neglected. The groundwater flow in an aquitard is assumed to be predominantly vertical. An aquifuge is a geological formation with low permeability and porosity. This does not transmit any groundwater and does not contain groundwater in appreciable quantities.

See also: Aquifer, Geohydrology, Groundwater Aquifer.

Aquifer

An aquifer is a water-bearing subsurface zone in which the vertical flow component is so small with respect to the horizontal flow component that it can be neglected.

The groundwater flow in an aquifer is assumed to be predominantly horizontal. The term aquifer is synonymous with water-bearing formation. An aquifer may be porous rock, unconsolidated gravel, fractured rock, or cavernous limestone. Economically important amounts of water may vary from less than a gallon per minute for cattle water in the desert to thousands of gallons per minute for industrial, irrigation, or municipal use.

Aquifers are important reservoirs storing large amounts of water relatively free from evaporation loss or pollution. If the annual withdrawal from an aquifer regularly exceeds the replenishment from rainfall or seepage from streams, the water stored in the aquifer will be depleted. Lowering the pressure in an aquifer by overpumping may cause the aquifer and confining layers of silt or clay to be compressed under the weight of the overburden. The resulting subsidence of the ground surface may cause structural damage to the aquifer and to surface buildings, damage to wells, and other problems.

Depending on the permeability of the layers bordering the aquifer, a distinction is made between: (i) a confined aquifer, (ii) a semi-confined aquifer, (iii) an unconfined aquifer, and (iv) a semi-unconfined aquifer.

A confined aquifer is an aquifer in which groundwater is held under pressures greater than atmospheric pressure by upper and lower confining layers, forcing water to rise in wells to heights above the top of the aquifer (artesian wells; also known as an artesian aquifer). The confined aquifer is typically sandwiched between two impermeable layers of rock or sediments and are recharged only in those areas where the aquifer intersects the land surface. The pressure of the water in confined aquifers is higher than atmospheric pressure, which is why when a well is bored into the aquifer, the water rises up the well tube, to a level higher than the aquifer.

If the water level in an artesian well stands above the land surface, the well is a flowing artesian well. A particular aquifer at one place may be a confined aquifer but in other places may behave as an un-confined aquifer, when the water level falls below the base of the overlying confining layer. In the igneous and metamorphic rocks, groundwater may occur in confined conditions in joints and fractures. In volcanic rocks, the interflow spaces and the vesicular beds form confined aquifers. Examples of flowing artesian wells are found in the hard rock areas of South India.

A semi-confined aquifer is an aquifer that is situated between confining layers with a lower permeability. The upper (and lower) confining layers are semi-pervious, through which vertical leakage takes place due to head difference. These transmit limited quantities of groundwater. The general direction of flow in a semi-confined aquifer is horizontal. The preferred direction of flow in the confining layers above and below is vertical.

An unconfined aquifer is not overlain by any confining layer, but it has a confining layer at its bottom and is recharged by water seeping down from above in the form of rainfall and snow melt. Thus, an unconfined aquifer is a partly saturated aquifer bounded below by an aquiclude and above by the free water table or phreatic surface. At the free water table, the groundwater is at atmospheric pressure. In general, the water level in a well penetrating an unconfined aquifer does not rise above the water table, except when there is vertical flow. The unconfined aquifer is normally partly saturated with water, and the top of the saturated surface is known as the water table, which is under atmospheric pressure – it is also known as a water table/phreatic aquifer. The water level in wells penetrating this aquifer indicates the position of the water table in the surrounding aquifer.

A semi-unconfined aquifer (also known as leaky aquifer) is an aquifer which exhibits characters in between semi-confined and unconfined aquifers as the permeability of the fine grained overlying layers is more than in a semiconfined aquifer and the horizontal flow component in it cannot be neglected. This type of aquifer is a completely saturated aquifer that is bounded below by an aquiclude and above by an aquitard.

If the overlying aquitard extends to the land surface, the aquifer may be partly saturated, but if the aquifer is overlain by an unconfined aquifer that is bounded above by the water table, the aquifer will be fully saturated. If there is hydrological equilibrium, the piezometric level in a well tapping a leaky aquifer may coincide with the water table. In areas with upward or downward flow (i.e., in discharge or recharge areas) the piezometric level may rise above or fall below the water table.

Finally, a multi-layered aquifer is a succession of leaky aquifers sandwiched between aquitards. Systems of inter-bedded permeable and less permeable layers are common in deep sedimentary basins.

Aromatic Hydrocarbons

An aromatic hydrocarbon (sometimes referred to as an arene) is a hydrocarbon of which the molecular structure incorporates one or more planar sets of six carbon atoms that are connected by delocalized electrons numbering the same as if they consisted of alternating single and double covalent. Aromatic hydrocarbons contain carbon and hydrogen atoms only.

Benzene (C_6H_6) is the least complex aromatic hydrocarbon, and it was the first one named as such. Each carbon atom in the hexagonal cycle has four electrons to share. One goes to the hydrogen atom, and one to each of the two neighboring carbon atoms which leaves one electron to share with one of the two neighboring carbon atoms, thus creating a double bond with one carbon and leaving a single bond with the other, which is why some representations of the benzene molecule portray it as a hexagon with alternating single and double bonds.

After benzene, aromatic hydrocarbons can be polycyclic (also called condensed aromatic systems) (Figure A-3):

Figure A-3 Examples of aromatic hydrocarbons showing the alternating double bonds and single bonds.

Other depictions of the structure portray the hexagon with a circle inside it, to indicate that the six electrons are floating around in delocalized molecular orbitals the size of the ring itself. This represents the equivalent nature of the six carbon-carbon bonds all of bond order 1.5; the equivalency is explained by resonance forms. The electrons are visualized as floating above and below the ring, with the electromagnetic fields they generate acting to keep the ring flat.

The general properties of aromatic hydrocarbons are: (i) they display aromaticity, (ii) the carbon-hydrogen ratio is high, (iii) they burn with a strong sooty yellow flame because of the high carbon-hydrogen ratio, and (iv) they undergo electrophilic substitution reactions and nucleophilic substitution reaction.

Arsenic and Selenium

Arsenic is a notoriously poisonous metalloid with many allotropic forms, including a yellow (molecular non-metallic) and several black and gray forms (metalloids). Three metalloid forms of arsenic, each with a different crystal structure, are found free in nature. However, it is more commonly found as arsenide and in arsenate compounds, several hundreds of which are known. Arsenic and its compounds are used as pesticides, herbicides, insecticides, and in various alloys.

Selenium a nonmetal, chemically related to sulfur and tellurium, which rarely occurs in its elemental state in nature. Isolated selenium occurs in several different forms, the most stable of which is a dense purplish-gray semi-metal (semiconductor) form that is structurally a trigonal polymer chain. It conducts electricity and is used in photocells. Selenium is found in economic quantities in sulfide ores such as pyrite FeS_2 , partially replacing the sulfur in the ore matrix. Minerals that are selenide or selenate compounds are also known, but all are rare.

Selenium salts are toxic in large amounts, but trace amounts of the element are necessary for cellular function in most, if not all, animals, forming the active center of the enzymes glutathione peroxidase and thioredoxin reductase (which indirectly reduce certain oxidized molecules in animals and some plants) and three known deiodinase enzymes (which convert one thyroid hormone to another).

Arsenic and selenium occur in biomass to the extent of several parts per million and, on combustion of the coal, a varying quantity of these elements are released or retained in the ash, depending largely on the conditions under which the combustion takes place and on the nature of the ash.

Arsenic and selenium are determined by mixing a weighed sample with the Eschka mixture followed by ignition 750°C (1,380°F). The mixture is dissolved in hydrochloric acid, and the gaseous hydride of each element is generated from the appropriate oxidation state and determined by atomic absorption spectrophotometry. The method permits measurement of the total arsenic and selenium content of coal for the purpose of evaluating these elements where they can be of concern, for example, in coal combustion. When coal samples are prepared for analysis in accordance with standard procedure, the arsenic and selenium are quantitatively retained and are representative of the total amounts in the coal

Asabe Standard X593

The American Society of Agricultural and Biological Engineers (ASABE) is an educational and scientific organization dedicated to the advancement of engineering applicable to agricultural, food, and biological systems. Founded in 1907 and headquartered in St Joseph, Michigan, ASABE comprises 9,000 members in more than 100 countries. ASABE membership is open to all (engineers as well as non-engineers) who are interested in the knowledge and application of engineering in agricultural, food, and biological systems.

ASABE Standard X593 is the standard introduced by the American Society of Agricultural and Biological Engineers (ASABE) entitled "Terminology and Definitions for Biomass Production, Harvesting and Collection, Storage, Processing, Conversion and Utilization."

The purpose of the standard is to provide uniform terminology and definitions in the general area of biomass production and utilization. This standard includes many terminologies that are used in biomass feedstock production, harvesting, collecting, handling, storage, pre-processing and conversion, bioenergy, biopower, and bioproducts. The terminologies were reviewed by many experts from all of the different fields of biomass and bioenergy before being accepted as part of the standard.

See also: Biomass.

Ash

Ash is the noncombustible residue remaining after complete combustion of a fuel and is composed primarily of oxides and sulfates, and it should not be confused with mineral matter, which is composed of the unaltered inorganic minerals in the fuel. In very general terms, the inorganic materials in most solid fuels, including biomass, can be divided into two broad fractions: (i) inherent inorganic material and (ii) extraneous inorganic material.

The inherent inorganic material exists as part of the organic structure of the fuel, and is most commonly associated with the oxygen-, sulfur-, and nitrogen-containing functional groups. These organic functional groups can provide suitable sites for the inorganic species to be associated chemically in the form of cations or chelates. Biomass materials tend to be relatively rich in oxygen-containing functional groups, and a significant fraction of the inorganic material in some of the lower ash biomass fuels is commonly in this form. It is also possible for inorganic species to be present in fine particulate form within the organic structure of some of the fuels, and to behave essentially as an inherent component of the fuel.

The extraneous inorganic material has been added to the fuel through geological processes, or during harvesting, handling, and processing of the fuel. Biomass fuels, for instance, are commonly contaminated with soil and other materials, which have become mixed with the fuel during collection, handling and storage.

Ash is quantitatively and qualitatively different from the mineral matter originally present in the fuel because of the various changes that occur, such as loss of water from silicate minerals, loss of carbon dioxide from carbonate minerals, oxidation of iron pyrite to iron oxide, and fixation of oxides of sulfur by bases such as calcium and magnesium. In fact, incineration conditions determine the extent to which the weight changes take place and it is essential that standardized procedures be closely followed to ensure reproducibility.

Thus, ash is formed as the result of chemical changes that take place in the mineral matter during the *ashing* process. The quantity of ash can be more than, equal to, or less than the quantity of mineral matter in the fuel, depending on the nature of the mineral matter and the chemical changes that take place in ashing. The various changes that occur include (i) loss of water from silicate minerals, (ii) loss of carbon dioxide from carbonate minerals, (iii) oxidation of iron pyrite to iron oxide, and (iv) fixation of oxides of sulfur by bases such as calcium and magnesium. In fact, incineration conditions determine the extent to which the weight changes take place and it is essential that standardized procedures be closely followed to ensure reproducibility.

The use of fuel with mineral matter that gives a high alkali oxide ash often results in the occurrence of slagging and fouling problems, especially in gasifiers. As oxides, most ash elements have high melting points, but they tend to form complex compounds (often called eutectic mixtures) that have relatively low melting points. On the other hand, high-calcium-low-iron ash coals tend to exhibit a tendency to produce low-melting range slag, especially if the sodium content of the slag exceeds approximately 4% w/w.

The chemical composition of the ash is an important factor in fouling and slagging problems and in the viscosity of ash in wet bottom and cyclone furnaces. The potential for the mineral constituents to react with each other as well as undergo significant mineralogical changes is high. In addition, fuel with a high iron content (usually >20% w/w ferric oxide) ash typically exhibits ash-softening temperatures under 1,205°C (2,200°F). Also, volatile alkali compounds lower the fusion temperature of ash. In conventional combustion equipment having furnace gas exit temperatures above 790°C (1,450°F, combustion of agricultural residue causes slagging and deposits on heat transfer surfaces. Specially designed boilers with lower furnace exit temperatures could reduce slagging and fouling from combustion of these fuels. Low-temperature gasification may be another method of using these fuels for efficient energy production while avoiding the slagging and fouling problems encountered in direct combustion.

In some test methods, it is recommended that the color of the ash should be noted as it gives an approximate indication of the fusion point. Generally, highly colored ash has a low fusion point while white ash, provided they are relatively no basic oxides, has a high fusion point.

See also: Biomass Ash, Bottom Ash, Fly Ash.

Ash Analysis

Ash analyses are used for evaluation of the corrosion, slagging, and fouling potential of ash. Typically, the ash constituents of interest are silica (SiO_2), alumina (Al_2O_3), titania (TiO_2), ferric oxide (Fe_2O_3), lime (CaO), magnesia (MgO), potassium oxide (K_2O), sodium oxide (Na_2O), and sulfur trioxide (SO_3). An indication of ash behavior can be estimated from the relative percentages of each constituent.

The determination of mineral ash in a fuel is usually by heating (burning) an accurately-weighed sample of the coal in an adequately ventilated muffle furnace at temperatures in the range 700 to 750°C (1,290 to 1,380°F) for 4 hours. Typically, the experimental data should be reproducible within $\pm 0.2\%$ of the end result. Other standard test methods may vary and require somewhat higher temperatures for the determination of the ash in coal.

See also: Ash, Ash Content.

Ash Composition

The chemical composition of ash is an important factor in fouling and slagging problems and in the viscosity of ash in wet bottom and cyclone furnaces. The potential for the mineral constituents to react with each other as well as undergo significant mineralogical changes is high. The use of biomass feedstocks with mineral matter that gives a high alkali oxide ash often results in the occurrence of slagging and fouling problems. As oxides, most ash elements have high melting points, but they tend to form complex compounds (often called eutectic mixtures) which have relatively low melting points. On the other hand, high-calcium-low-iron ash coals exhibit a tendency to produce low-melting range slags, especially if the sodium content of the slag exceeds approximately 4% w/w.

One form of ash is fly ash, one of the residues generated during combustion. Fly ash is generally captured from the chimneys of power plants, and is one of two types of ash that are jointly known as ash; the other form of coal ash is bottom ash, which is removed from the bottom of coal furnaces.

Depending upon the source and makeup of the feedstock to the combustor, the components of fly ash vary considerably (Table A-24), but all fly ash includes substantial amounts of silicon dioxide (SiO_2) (both amorphous and crystalline) and calcium oxide (CaO), both being endemic ingredients in many coal bearing rock strata.

Table A-24 Common constituents of fly ash (% w/w).

Coal:	Bituminous	Subbituminous	Lignite
SiO_2	20-60	40-60	15-45
Al_2O_3	5-35	20-30	20-25
Fe_2O_3	10-40	4-10	4-15
CaO	1-12	5-30	15-40

Toxic constituents depend upon the specific coal bed makeup, but may include one or more of the following elements or substances (in alphabetical order and not in order of occurrence) in quantities from trace amounts to several percent: arsenic, beryllium, boron, cadmium, chromium, cobalt, lead, manganese, mercury, molybdenum, selenium, strontium, thallium, and vanadium. Organic constituents of ash include dioxins and polynuclear aromatic compounds.

Fly ash solidifies while suspended in the exhaust gases and is collected by electrostatic precipitators or filter bags (Baghouse). Since the particles solidify while suspended in the exhaust gases, fly ash particles are generally spherical in shape and range in size from 0.5 micron to 100 μm . They consist mostly of silica (SiO_2), which is present in two forms: amorphous (rounded and smooth) and crystalline (sharp, pointed, and hazardous), aluminum oxide (Al_2O_3), and iron oxide (ferric oxide, Fe_2O_3). Fly ash is generally highly heterogeneous and consisting of a mixture of glassy particles with various identifiable crystalline phases such as quartz, mullite ($3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$ or $2\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$), and various iron oxides.

In the past, fly ash was generally released into the atmosphere, but pollution control equipment mandated in recent decades now requires that it be captured prior to release. In the United States, fly ash is generally stored or placed in landfills or is often used to supplement Portland cement in concrete production as well as in the synthesis of geopolymers and zeolites.

Ash Content

Ash content (which is a thermal manifestation of the inorganic content of a fuel, such as biomass) is the inorganic oxides that remain after complete combustion of the feedstock. The amount of ash between different types of feedstocks differs widely (0.1% w/w for wood and up to 15% w/w for some agricultural products) and influences the use of the fuel as well as the design of the reactor, particularly the ash removal system. The chemical composition of the ash is also important because it affects the melting behavior of the ash. Ash melting can cause slagging and channel formation in the reactor. Slag can ultimately block the entire reactor.

Generally, the ash-forming inorganic materials in most solid fuels, including biomass, can be divided into two broad fractions: (i) the inherent inorganic material and (ii) the extraneous inorganic material.

The inherent inorganic material exists as part of the organic structure of the fuel, and is most commonly associated with the oxygen-, sulfur-, and nitrogen-containing functional groups. These organic functional groups can provide suitable sites for the inorganic species to be associated chemically in the form of cations or chelates. Biomass materials tend to be relatively rich in oxygen-containing functional groups, and a significant fraction of the inorganic material in some of the lower ash biomass fuels is commonly in this form. It is also possible for inorganic species to be present in fine particulate form within the organic structure of some of the fuels, and to behave essentially as an inherent component of the fuel.

The extraneous inorganic material has been added to the fuel through geological processes, or during harvesting, handling, and processing of the fuel. Biomass fuels, for instance, are commonly contaminated with soil and other materials, which have become mixed with the fuel during collection, handling, and storage.

The most commonly applied technique for the determination of the ash content and ash composition of coals and other solid fuels in the laboratory involves heating the fuel slowly in air to constant mass at a temperature of 815°C (1,500°F), and subjecting the resultant ash residue to chemical elemental analysis. The ash residue is normally weighed to provide an estimate of the ash content of the fuel, and then analyzed for the 10 major elements present in coal ashes, i.e., Si, Al, Fe, Ca, Mg, Ti, Na, K, P, and S. The elemental concentrations are conventionally expressed as oxides, in their highest oxidation states. The analysis of the laboratory-prepared ash for its trace element content is also fairly common practice. This is a perfectly reasonable and practical approach for most coals, and many other solid fuels, and has been applied for biomass ash analysis.

Biomass feedstocks and fuels exhibit a wide range of physical and chemical properties (Table A-25), but despite the wide range of possible sources, biomass feedstocks are remarkably uniform in many of their fuel properties, compared with competing feedstocks such as coal or crude oil. For example, there are many types of coal whose gross heating value ranges from 8,600 to 12,900 Btu/lb). However, nearly all kinds of biomass feedstocks destined for combustion fall in the range 6,450 to 8,200 Btu/lb). For most agricultural residues, the heating values are even more uniform – approximately 6,450 to 7,300 Btu/lb. The values for most woody materials fall into the range 7,750 to 8,200 Btu/lb.

Table A-25 Properties of biomass and other fuel sources.

		Chemical Characteristics			
		Ash, %	Sulfur, % w/w	Potassium, % w/w	Ash melting temperature (°C)
Bioenergy Feedstocks	corn stover	5.6

The most commonly applied technique for the determination of the ash content and ash composition of coals and other solid fuels in the laboratory involves heating the fuel slowly in air to constant mass at a temperature of

815°C (1,500°C), and subjecting the resultant ash residue to chemical elemental analysis. The ash residue is normally weighed to provide an estimate of the ash content of the fuel, and then analyzed for the 10 major elements present in coal ashes, i.e., Si, Al, Fe, Ca, Mg, Ti, Na, K, P, and S. The elemental concentrations are conventionally expressed as oxides, in their highest oxidation states. The analysis of the laboratory-prepared ash for its trace element content is also fairly common practice. This is a perfectly reasonable and practical approach for most coals, and many other solid fuels, and has been applied for biomass ash analysis.

See also: Biomass.

Ash Content – Biomass

Ash content (which represents inorganic content) of biomass is the inorganic oxides that remain after complete combustion of the feedstock. The amount of ash between different types of feedstocks differs widely (0.1% for wood up to 15% for some agricultural products) and influences the design of the reactor, particularly the ash removal system. The chemical composition of the ash is also important because it affects the melting behavior of the ash. Ash melting can cause slagging and channel formation in the reactor. Slag can ultimately block the entire reactor.

Generally, the ash-forming inorganic materials in most solid fuels, including biomass, can be divided into two broad fractions, viz: (i) the inherent inorganic material and (ii) the extraneous inorganic material.

The inherent inorganic material, which exists as part of the organic structure of the fuel, and is most commonly associated with the oxygen-, sulfur-, and nitrogen-containing functional groups. These organic functional groups can provide suitable sites for the inorganic species to be associated chemically in the form of cations or chelates. Biomass materials tend to be relatively rich in oxygen-containing functional groups, and a significant fraction of the inorganic material in some of the lower ash biomass fuels is commonly in this form. It is also possible for inorganic species to be present in fine particulate form within the organic structure of some of the fuels, and to behave essentially as an inherent component of the fuel.

The extraneous inorganic material, which has been added to the fuel through geological processes, or during harvesting, handling, and processing of the fuel. Biomass fuels, for instance, are commonly contaminated with soil and other materials, which have become mixed with the fuel during collection, handling and storage.

The most commonly applied technique for the determination of the ash content and ash composition of coals and other solid fuels in the laboratory involve heating the fuel slowly in air to constant mass at a temperature of 815°C (1,500°F), and subjecting the resultant ash residue to chemical elemental analysis. The ash residue is normally weighed to provide an estimate of the ash content of the fuel, and then analyzed for the 10 major elements present in coal ashes, i.e., Si, Al, Fe, Ca, Mg, Ti, Na, K, P, and S. The elemental concentrations are conventionally expressed as oxides, in their highest oxidation states. The analysis of the laboratory-prepared ash for its trace element content is also fairly common practice. This is a perfectly reasonable and practical approach for most coals, and many other solid fuels, and has been applied for biomass ash analysis.

Biomass feedstocks and fuels exhibit a wide range of physical and chemical properties (Table A-25), but despite the wide range of possible sources, biomass feedstocks are remarkably uniform in many of their fuel properties. However, nearly all kinds of biomass feedstocks destined for combustion fall in the range 6,450 to 8,200 Btu/lb). For most agricultural residues, the heating values are even more uniform – approximately 6,450 to 7,300 Btu/lb. The values for most woody materials fall into the range 7,750 to 8,200 Btu/lb.

The most commonly applied technique for the determination of the ash content and ash composition of coals and other solid fuels in the laboratory involves heating the fuel slowly in air to constant mass at a temperature of 815°C (1,500°F), and subjecting the resultant ash residue to chemical elemental analysis. The ash residue is normally weighed to provide an estimate of the ash content of the fuel, and then analyzed for the 10 major elements present in coal ashes, i.e. Si, Al, Fe, Ca, Mg, Ti, Na, K, P, and S. The elemental concentrations are conventionally expressed as oxides, in their highest oxidation states. The analysis of the laboratory-prepared ash for its trace element content is also fairly common practice. This is a perfectly reasonable and practical approach for most coals, and many other solid fuels, and has been applied for biomass ash analysis.

See also Ash, Ash Composition.

As-Received Moisture

The as-received moisture of a carbonaceous samples is the moisture present in a sample when delivered to the analytical laboratory or to the customer. Moisture content can affect the self-heating rate of the sample in two ways: changing the overall heat balance and the rate of the oxidation reaction.

It has been suggested that there is a critical moisture content at which the rate of oxidation reached a maximum, but the reaction may be subject to the means of conducting the test which can change the subsequent low-temperature oxidation behavior of the sample.

Atmosphere

The atmosphere is the envelope of gases surrounding the earth, and it is subdivided into regions depending on the altitude. The constituents of the atmosphere are primarily nitrogen (N_2 , 78.08% v/v), oxygen (O_2 , 20.95% w/w), and water vapor (0 to 0.25% w/w), although the concentration of water vapor (H_2O) is highly variable, especially near the surface, where volume fractions can be as high as 4% in the tropics. There are many minor constituents or trace gases such as (alphabetically rather than by abundance, which is variable) argon (Ar), carbon dioxide (CO_2), helium (He), hydrogen (H_2), krypton (Kr), methane (CH_4), (neon, Ne), nitrous oxide (N_2O), ozone (O_3), and water vapor (H_2O) (Table A-26).

Table A-26 Approximate Composition of the Atmosphere.

Component, % v/v	Amount, % v/v
Major components:	
Nitrogen (N_2)	78.08
Oxygen (O_2)	20.95
Minor/trace components:	
Argon (Ar)	0.93
Water vapor (H_2O)	0.025*
Carbon dioxide (CO_2)	0.035
Neon (Ne)	0.018
Helium (He)	0.00052
Methane (CH_4)	0.00014
Krypton (Kr)	0.00010
Nitrous oxide (N_2O)	0.00005
Hydrogen (H_2)	0.00005
Ozone (O_3)	0.0000007

*Variable; can be as high as 4% v/v in humid areas.

In addition to the gaseous constituents, the atmosphere also contains suspended solid and liquid particles. Aerosols are particulate matter usually less than 1 micron in diameter (also called $1\ \mu m$ which is equivalent to $1\ m \times 10^{-6}$ in diameter, i.e., one millionth of a meter or one thousandth of a millimeter, 0.001 mm, or approximately 0.000039 of an inch) that are created by gas-to-particle reactions and are lifted from the surface by the winds. A portion of these aerosols can become centers of condensation or deposition in the growth of water and ice clouds. Cloud droplets and ice crystals are made primarily of water with some trace amounts of particles and dissolved gases. Their diameters

range up to 100 μm . Water or ice particles larger than approximately 100 microns begin to fall because of gravity and may result in precipitation at the surface.

Ozone is found in trace quantities throughout the atmosphere, the largest concentrations being location in a layer in the lower stratosphere between the altitudes of 9 and 18 mi (15 and 30 km). This ozone results from the dissociation by solar ultraviolet radiation of molecular oxygen in the upper atmosphere and nitrogen dioxide in the lower atmosphere. Ozone also plays an important role in the formation of photochemical smog and in the purging of trace species from the lower atmosphere.

The chemistry of ozone formation can be explained in relatively simple terms, although the reactions are believed to be much more complex. Thus, above approximately 19 mi (30 km), oxygen is dissociated during the daytime by energy ($h\nu$) from ultraviolet light:

The oxygen atoms produced then form ozone:

In this equation, M is an arbitrary molecule required to conserve energy and momentum in the reaction that produces ozone. Although present in only trace quantities (Table A-26), atmospheric ozone plays a critical role for the biosphere by absorbing the ultraviolet radiation with a wavelength from 240 to 320 nm (nm, 1 nm = 1 meter $\times 10^9$, which would otherwise be transmitted to the surface of the Earth.

The atmospheric ozone should not be confused with the ozone layer which acts as a region of stratosphere of the Earth that absorbs most of the ultraviolet radiation from the Sun. The ozone layer is mainly found in the lower portion of the stratosphere, from approximately 9 to 22 mi above the Earth, although the thickness of the layer varies seasonally and geographically. This layer is so-named because it contains a high concentration of ozone (O_3) in relation to other parts of the atmosphere, although still small in relation to other gases in the stratosphere. The ozone layer contains up to 10 parts per million of ozone, while the average ozone concentration in the atmosphere of the Earth as a whole is on the order of 0.3 parts per million.

The ultraviolet radiation is lethal to simple unicellular organisms (algae, bacteria, protozoa) and to the surface cells of higher plants and animals. It also damages the genetic material of cells (deoxyribonucleic acid, DNA) and is responsible for sunburn in human skin. In addition, the incidence of skin cancer has been statistically correlated with the observed surface intensities of the ultraviolet wavelengths from 290 to 320 nm, which are not totally absorbed by the ozone layer.

Atmospheric pressure decreases as an approximately exponential function of altitude, which largely determines the characteristics of the atmosphere. Thus:

$$P_h = P_o e^{mgh/RT}$$

In this equation, P_h is the pressure at any given height, P_o is the pressure at zero altitude (sea level); m is the average gram molecular mass of air (28.97 g/mole in the troposphere); g is the acceleration of gravity (981 $\text{cm} \times \text{sec}^{-1}$ at sea level); h is the altitude (in cm or meters or kilometers), and R is the gas constant (8.314 $\times 10^7 \text{ erg} \times \text{deg}^{-1} \times \text{mole}^{-1}$), and T is the absolute temperature. Furthermore:

$$\log P_h = \log P_o - (mgh \times 10^5)/2.303RT$$

At sea level where the pressure is 1 atm:

$$\log P_h = (mgh \times 10^5)/2.303RT$$

The characteristics of the atmosphere vary widely with altitude, time (season), location (latitude), and even solar activity. At a high altitude, normally reactive species, such as atomic oxygen, persist for long periods of time. At such

altitudes, the pressure is low and the distance traveled by a reactive species before it collides with a potential reactant (the mean free path) is high.

An important effect noted as a result of the changes in the constituents of the atmosphere is the tendency for the temperature close to the surface of the Earth to rise, a phenomenon referred to as the greenhouse effect. This term is used to describe the rise in the temperature of the earth, analogous to the rise in temperature in a greenhouse when the energy from the sun is trapped and cannot escape from the enclosed space. Although the term greenhouse effect has generally been used for the role of the whole atmosphere (mainly water vapor and clouds) in keeping the surface of the earth warm, it has been increasingly associated (perhaps erroneously) with the contribution of carbon dioxide. However, there are various types of gases that are the result of industrial and domestic activities that can contribute to this effect and, thus, the continual rise in the surface temperature of the earth.

The arguments related to the magnitude of the greenhouse effect have ranged back and forth for some time with carbon dioxide as the main (if not the sole) cause without recognition of other causes, several of which are natural causes or events. There are those who believe that the Earth is doomed to a rise in temperature and serious harm to the human race is imminent. On the other hand, there are those observers who believe that there is no cause for concern related to the environment and humans can go on merrily as has been the case for centuries and polluting the atmosphere without any concerns related to the consequences of such actions. Whatever the correct side on which to base an argument, there is no doubt that the emissions, which can give rise to such an effect, must be limited. The continuous pollution of the atmosphere with the so-called greenhouse gases can be of no advantage to life on earth, even if the effects of these gases are not manifested in a temperature rise but in the form of aggravating pollutants to flora and fauna.

Both of these opposite opinions are of some concern because they may mask the reality of the situation. It is analogous to other situations that have arisen in the last several decades. For example, in the late 1960s and early 1970s, there were warnings related to an approaching ice age. In fact, they were those observers who would have us believe that, upon looking out of the window, an observer(s) would see glaciers approaching from the end of the street! In fact, it is entirely likely that several important analysts who then warned of global cooling and imminent glaciation of northern societies are now warning of global warming. The glaciers did not arrive and now, in a little more fifty years later, the frantic warnings are not related to a rise in global temperature! There are also advisories that the rise in temperature that is the basis of global warming is being accompanied (perceived or real) by the emergence (or reemergence) of a variety of infectious diseases. If, as has been suggested, the Earth has warmed 0.3 to 0.6°C (approximately 1°F, or less) during this century, the perception is that a higher rise in the temperature of the earth may lead to a series of global catastrophes.

These types of contradictory reports and arguments add much confusion to an already difficult area of technology. It seems that every time a government appropriates money to study an issue, the heretofore unheard-of-experts spring into action. What is really needed is a careful study of the data, the generation of new data, and less enthusiasm for catching the headlines.

Chemicals can be emitted directly into the atmosphere or formed by chemical conversion through chemical reactions of precursors species. In these reactions, highly toxic chemicals can be converted into less toxic products, but the result of the reactions can also be products having a higher toxicity than the starting chemicals. In order to understand these reactions, it is also necessary to understand the chemical composition of the natural atmosphere, the way gases, liquids, and solids in the atmosphere interact with each other and with the surface of the Earth and associated biota, and how human activities may be changing the chemical and physical characteristics of the atmosphere.

There are a number of critical environmental issues associated with a changing atmosphere, including photochemical smog, global climate change, toxic air pollutants, acidic deposition, and stratospheric ozone depletion. Much of the anthropogenic (human) impact on the atmosphere is associated with the increasing use of fossil fuels as an energy source – for things such as heating, transportation, and electric power production. Photochemical smog/tropospheric ozone is a serious environmental problem that has been associated with burning such fuels, and the result has been the formation and deposition of acid rain.

Acid rain is formed when sulfur oxides and nitrogen oxides react with water vapor and other chemicals in the presence of sunlight to form various acidic compounds in the atmosphere. The principal source of acid rain-causing

pollutants, sulfur oxides and nitrogen oxides, is from fuel combustion – specifically from fuels that contain sulfur and nitrogen:

sulfurous acid

sulfuric acid

nitrous acid

nitric acid

Two of the pollutants that are emitted are hydrocarbon derivatives (e.g., unburned fuel) and nitric oxide (NO). When these pollutants build up to sufficiently high levels, a chain reaction occurs from their interaction with sunlight in which the NO is converted to nitrogen dioxide (NO₂) – a brown gas and at sufficiently high levels can contribute to urban haze. However, a more serious problem is that nitrogen dioxide (NO₂) can absorb sunlight and break apart to produce oxygen atoms that combine with the oxygen in the air to produce ozone (O₃), a powerful oxidizing agent, and a toxic gas.

In addition, as a result of a variety of human activities (e.g., agriculture, transportation, industrial processes) a large number of different toxic chemical pollutants are emitted into the atmosphere. Among the chemicals that may pose a human health risk are pesticides, polychlorobiphenyl derivatives (PCBs), polycyclic aromatic hydrocarbon derivatives (PAHs), dioxin derivatives, and volatile compounds (e.g., benzene, carbon tetrachloride).

Polychlorobiphenyl derivatives; *n* and *m* can be any number from 1 to 5.

1,4-Dioxin

1,2-Dioxin

Polychlorinated dibenzo-p-dioxin derivatives; n and m can be any number from 1 to 5.

Many of the more environmentally persistent compounds (such as the polychlorobiphenyl derivatives) have been measured in various floral and faunal species.

See also: Condensation.

Atmospheric Equivalent Boiling Point

The atmospheric equivalent boiling point is the boiling point at which a sample or fraction of a fuel would boil under atmospheric pressure if it was stable and would not decompose. This provides a common basis for the categorization and direct comparison of petroleum components across the entire volatility range accessible by atmospheric and vacuum distillation.

Distillation at lower pressure allows high-boiling fractions to distill at lower temperatures, thereby foregoing the potential of thermal decomposition if attempts were made to distill the fraction at the higher temperatures required at atmospheric pressure. This allows the collection of distillates with an atmospheric equivalent temperature cut point of as high as 560°C (1050°F). The actual observed boiling points during this distillation are, of course, much lower. Despite the low pressure, the reboiler may have to be heated as high as 370°C (700°F) for such high-boiling distillates.

Molecular distillation is a non-equilibrium process and the atmospheric equivalent boiling range of a fuel or a fraction of a fuel that cannot be measured directly. The atmospheric equivalent boiling point (AEBP) concept was developed to compensate for this and can be estimated from one of the following equations:

$$\text{mid-AEBP } (^{\circ}\text{F}) = \{[(M_n - 140)(\text{sp. gr.})^{2.5/3.40}] \times 10^7\}^{1/3}$$

$$\text{mid-AEBP } (^{\circ}\text{F}) = \{[(M_n - 170)(\text{H/C})^{0.9/2.67}] \times 10^7\}^{1/3}$$

The mid-AEBP is the temperature for the 50% mass point on the distillation curve of the fraction, and M_n is the molecular weight. Either the specific gravity (sp. gr.) or atomic hydrogen/carbon (H/C) ratio, which can be readily measured in the fractions, can also be used. Using the mid-AEBP concept, even fractions of the non-distillable residue can be included in the boiling range curves and relationships such as the variation of sulfur and nitrogen contents can be derived as a function of the AEBP.

Typically, as the mid-AEBP increases, the sulfur and nitrogen concentrations of the fraction generally also increase. Also, the highest concentrations of both sulfur and nitrogen appear in the non-distillable fractions. This behavior follows the heteroatom behavior observed for refinery distillation cuts. Thus, the higher the boiling range of the fraction, the higher the heteroatom concentration. This also establishes that the heteroatom concentration continues to increase as the volatility of the compounds decreases, which was not known previously for the 540°C⁺ (1000°F⁺) residuum.

Atomic Energy

Atomic energy (or, more correctly, nuclear energy) is a term that represents the energy with an atom and includes (i) nuclear binding energy, (ii) nuclear potential energy, (iii) nuclear reaction, which is a process in which nuclei

or nuclear particles interact, resulting in products different from the initial ones, (iv) radioactive decay which is a descriptor for the various processes by which unstable atomic nuclei (nuclides) emit subatomic particles, and (iv) the energy of inter-atomic or chemical bonds, which holds atoms together in compounds.

Atomic energy is the source of nuclear power which uses sustained nuclear fission to generate heat and electricity. It is also the source of the explosive force of an atomic bomb. The energy originates from the splitting of uranium atoms (nuclear fission) which generates heat to produce steam, which is used by a turbine generator to generate electricity. Because nuclear power plants do not burn fuel, they do not produce greenhouse gas emissions but, caution is advised, and although the risk of accidents in nuclear power plants is low, the consequences of an accident can be drastic and highly detrimental to the surrounding flora and fauna (including human life).

Attapulgius Clay

Attapulgius clay (*attapulgiite* or *palygorskite*) is a magnesium aluminum phyllosilicate $[(\text{Mg},\text{Al})_2\text{Si}_4\text{O}_{10}\cdot 4\text{H}_2\text{O}]$ which occurs in a type of clay soil common to the Southeastern United States. It is one of the types of fuller's earth.

The name *attapulgiite* is derived from the U.S. town of Attapulgius, Georgia, in the extreme southwest corner of the state, where the mineral is abundant. It is surface-mined in the area, dry-ground and air-separated into precise particle sizes, and transported in covered hopper cars via the railroad, and is also shipped in 50-lb bags and bulk bags by truck. The name *palygorskite* is given after the place in the Ural Mountains where it was discovered.

Attapulgiite clays are swellable clays like bentonite, although more acicular (or needle like). Attapulgiite, unlike bentonite, will swell in salt water and is used in special salt water drilling mud for off shore oil drilling. Like many clays, they can be considered as charged particles with zones of positive and negative charges. Standard attapulgiite clays are agglomerated bundles of clay particles between 20 and 100 μm long and below 1 μm in diameter. Most grades contain up to 25% non-attapulgiite material in the form of mineral carbonates and other inclusions. The advantage of attapulgiites is that their performance is not temperature sensitive and they have lower water demand. They must have free ions in an aqueous system to work.

See also: Clay Minerals, Clay Treating Process.

Attrition Catalyst

Typically, a relatively inexpensive catalyst that is designed to remove impurities and unwanted by-products from gas streams which, at the same time, is sacrificed. For example, alumina (Al_2O_3) guard beds serve as protectors by the act of attrition and may be referred to as an attrition reactor containing an attrition catalyst may be placed ahead of the molecular sieves to remove the sulfur compounds. Downflow reactors are commonly used for adsorption processes, with an upward flow regeneration of the adsorbent and cooling using gas flow in the same direction as adsorption flow.

See also: Guard Bed, Guard Bed Reactor.

Azeotrope

Two main types of azeotropes exist, i.e., the *homogeneous azeotrope*, where a single liquid phase is in the equilibrium with a vapor phase; and the *heterogeneous azeotropes*, where the overall liquid composition which form two liquid phases, is identical to the vapor composition. Most methods of distilling azeotropes and low relative volatility mixtures rely on the addition of specially chosen chemicals to facilitate the separation.

The five methods for separating azeotropic mixtures are: (i) extractive distillation and homogeneous azeotropic distillation where the liquid separating agent is completely miscible, (ii) heterogeneous, (iii) azeotropic distillation, or more commonly, azeotropic distillation where the liquid separating agent (the entrained) forms one or more azeotropes with the other components in the mixture and causes two liquid phases to exist over a wide range of

compositions – this immiscibility is the key to making the distillation sequence work, (iv) distillation using ionic salts in which the salts dissociate in the liquid mixture and alters the relative volatilities sufficiently that the separation become possible, (iv) pressure-swing distillation in which a series of column operating at different pressures are used to separate binary azeotropes which change appreciably in composition over a moderate pressure range or where a separating agent which forms a pressure-sensitive azeotrope is added to separate a pressure-insensitive azeotrope, and (v) reactive distillation where the separating agent reacts preferentially and reversibly with one of the azeotropic constituents; the reaction product is then distilled from the non-reacting components, and the reaction is reversed to recover the initial component, (v) simple distillation in which a multi-component liquid mixture is slowly boiled in a heated zone and the vapors are continuously removed as they form and, at any instant in time, the vapor is in equilibrium with the liquid remaining on the still; because the vapor is always richer in the more volatile components than the liquid, the liquid composition changes continuously with time, becoming more and more concentrated in the least volatile species.

A simple distillation residue curve is a means by which the changes in the composition of the liquid residue curves on the pot changes over time. Residue curve map is a collection of the liquid residue curves originating from different initial compositions. Residue curve maps contain the same information as phase diagrams, but represent this information in a way that is more useful for understanding how to synthesize a distillation sequence to separate a mixture.

All of the residue curves originate at the light (lowest boiling) pure component in a region, move toward the intermediate boiling component, and end at the heavy (highest boiling) pure component in the same region. The lowest temperature nodes are termed as unstable nodes, as all trajectories leave from them, while the highest temperature points in the region are termed stable nodes, as all trajectories ultimately reach them. The point that the trajectories approach from one direction and end in a different direction (as always is the point of intermediate boiling component) is termed saddle point. Residue curves that divide the composition space into different distillation regions are called distillation boundaries.

The separation of components of similar volatility may become economical if an *entrainer* can be found that effectively changes the relative volatility. It is also desirable that the entrainer be reasonably cheap, stable, non-toxic, and readily recoverable from the components. In practice, it is probably this last criterion that severely limits the application of extractive and azeotropic distillation. The majority of successful processes, in fact, are those in which the entrainer and one of the components separate into two liquid phases on cooling if direct recovery by distillation is not feasible.

A further restriction in the selection of an azeotropic entrainer is that the boiling point of the entrainer be in the range 10 to 40°C (18 to 72°F) below that of the components. Thus, although the entrainer is more volatile than the components and distills off in the overhead product, it is present in a sufficiently high concentration in the rectification section of the column.

See also: Azeotropic Distillation, Distillation.

Azeotropic Distillation

Azeotropic distillation is the use of a third component to separate two close-boiling components by means of the formation of an azeotropic mixture between one of the original components and the third component to increase the difference in the boiling points and facilitates separation by distillation.

All compounds have definite boiling temperatures, but a mixture of chemically dissimilar compounds sometimes causes one or both of the components to boil at a temperature other than that expected. For example, benzene boils at 80°C (176°F), but if it is mixed with hexane, it distills at 69°C (156°F). A mixture that boils at a temperature lower than the boiling point of either of the components is called an azeotropic mixture.

Chemical bonding between the components of the mixture creates properties unique to the mixture. If the system forms azeotropes, as in a benzene and cyclohexane system, a different problem arises - the azeotropic composition limit the separation, and for a better separation, this azeotrope must be bypassed in some way. At the azeotropic point, the mixture contains the given component in the same proportion as the vapor, so that evaporation does not

change the purity, and distillation does not affect separation. For example, ethyl alcohol and water form an azeotrope (azeotropic mixture) at 78.2°C (172.8°F).

If the separation of individual components from petroleum itself or from petroleum products is required, there are means by which this can be accomplished. For example, when a constant-boiling mixture of hydrocarbons contains components whose vapor pressure is affected differently by the addition of, say, a non-hydrocarbon compound, distillation of the hydrocarbon mixture in the presence of non-hydrocarbon additive may facilitate separation of the hydrocarbon components.

In general, the non-hydrocarbon additive is a polar organic compound and should also have the ability to form a binary minimum constant-boiling (or azeotropic) mixture with each of the hydrocarbons. Thus, it is often possible to separate compounds that have close boiling points by means of azeotropic distillation.

See also: Azeotrope, Distillation.

Bacteria

Bacteria are microscopic, single-celled organisms that thrive in diverse environments. These organisms can live in soil, the ocean, and inside the human digestive system. Bacteria are classified into five groups according to their basic shapes: (i) spherical shapes, also known as cocci, (ii) rod shapes, also known as bacilli, (iii) spiral shapes, also known as spirilla, (iv) comma shapes, also known as vibrios, and (v) corkscrew shapes, also known as spirochaetes which can also exist as single cells, in pairs, chains, or clusters.

Bacteria occur individually or grow as groups ranging from two to millions of individual cells. Individual bacteria cells are small and may be observed only through a microscope. Most bacteria fall into the size range of 0.5 to 3.0 microns ($1 \text{ micron} = 1 \text{ m} \times 10^{-6}$). However, considering all species, a size range of 0.3-50 microns is observed. In general, it is assumed that a filter with a pore size on the order of 0.45 micron will remove all bacteria from water passing through it.

The metabolic activity of bacteria is greatly influenced by their small size. Their surface-to-volume ratio is extremely large, so that the inside of a bacterial cell is accessible to a chemical substance in the surrounding medium. Thus, for the same reason that a finely divided catalyst is more efficient than a more coarsely divided one, bacteria may cause rapid chemical reactions compared to those mediated by larger organisms. Bacteria excrete enzymes that can act outside the cell (exoenzymes) that break down solid food material to soluble components which can penetrate bacterial cell walls, where the digestion process is completed.

Bacteria obtain the energy needed for their metabolic processes and reproduction by mediating redox reactions. Nature provides a large number of such reactions, and bacterial species have evolved that utilize many of these. As a consequence of their participation in such reactions, bacteria are involved in many biochemical processes in water and soil.

Bacteria are essential participants in many important elemental cycles in nature, including those of nitrogen, carbon, and sulfur. They are responsible for the formation of many mineral deposits, including some of iron and manganese. On a smaller scale, some of these deposits form through bacterial action in natural water systems and even in pipes used to transport water.

The presence of coliform bacteria, specifically *E. coli* (a type of coliform bacteria), in drinking water suggests the water may contain pathogens that can cause a variety of diseases and even death.

See also: Bacterial Mining.

Bacterial Mining

Bacterial mining, or bio-mining, represents the use of microorganisms to leach metals from ores or mine tailings (wastes), followed by the subsequent recovery of metals of interest from the leaching solution. The term has also been applied to the recovery of oil from reservoirs where the reservoir energy has been depleted over time. This could well be a process of the future for recovering energy from alternate sources that have been difficult-to-impossible to reach or recover and develop.

The use of microbes to extract metals from ores is simply the harnessing of a natural process for commercial purposes. Microbes have participated in the deposition and solubilization of heavy metals in the earth's crust since geologically ancient times. Most of this activity is linked to the iron and sulfur cycles. Anaerobic sulfate reducing bacteria generate sulfides that can react with a variety of metals to form insoluble metal sulfides. There are two main types of processes for commercial-scale microbially assisted metal recovery. These are irrigation-type and stirred tank-type processes. Bio-mining involves a chemical process called leaching which is actually oxidation reaction and maybe called bio-oxidation. Bio-leaching processes can be carried out at a range of temperatures, and as would be

expected, the iron- and sulfur-oxidizing microbes present differ depending on the temperature ranges. In mineral bio-oxidation processes that operate at 40°C or less, the most important microorganisms are believed to be a consortium of gram-negative bacteria such as *Acidithiobacillus ferrooxidans*. Microorganisms that dominate bio-leaching at 50°C (122°F) include *Acidithiobacillus caldus* and some *Leptospirillum* spp. At temperatures greater than 65°C (149°F), bio-mining microbial consortia are dominated by archaea rather than bacteria with species of *Sulfolobus* and Metallophores being most prominent.

Thus, biomining has developed into a successful and expanding area of biotechnology and the process employs microbial consortia that are dominated by acidophilic, autotrophic iron- or sulfur-oxidizing prokaryotes. Mineral bio-oxidation takes place in highly aerated, continuous-flow, stirred-tank reactors or in irrigated dump or heap reactors, both of which provide an open, non-sterile environment. Continuous-flow, stirred tanks are characterized by homogeneous and constant growth conditions where the selection is for rapid growth, and consequently, tank consortia tend to be dominated by two or three species of microorganisms. In contrast, heap reactors provide highly heterogeneous growth environments that change with the age of the heap, and these tend to be colonized by a much greater variety of microorganisms. Heap microorganisms grow as biofilms that are not subject to washout, and the major challenge is to provide sufficient biodiversity for optimum performance throughout the life of a heap.

Currently, a variety of biotechnological processes are being given serious consideration as options to the more conventional recovery methods for energy production. During the energy crisis that commenced in the 1970s, a bioleaching process was applied to oil shale in the United States in order to produce shale oil. Sulfur is actually introduced to the fractured oil shale blocks, and *Thiobacilli thiooxidans* is used to generate a large amount of 0.1 N sulfuric acid to remove carbonate minerals. With Green River oil shale, 43% of the carbonates can be removed so that a more porous oil shale rock will remain. More oil can be produced from this treatment method due to the improved heat transfer efficiency upon retorting.

Bagasse

Bagasse is the dry pulpy residue left after the extraction of juice from sugar cane, used as fuel for electricity generators and other forms of energy. In addition, bagasse is 100% compostable, and if it does enter our environment, it will break down into soil entirely naturally, without any human intervention or additional processing.

More specifically, bagasse is the fibrous residue remaining after sugarcane or sorghum stalks are crushed to extract their juice and is currently used as a renewable resource in the manufacture of pulp and paper products and building materials. Bagasse is often used as a primary fuel source for sugar mills; when burned in quantity, it produces sufficient heat energy to supply all the needs of a typical sugar mill, with energy to spare. To this end, a secondary use for this waste product is in cogeneration, the use of a fuel source to provide both heat energy, used in the mill, and electricity, which is typically sold to the consumer electricity grid.

Sugarcane bagasse is the major by-product of the sugar cane industry and contains approximately 50% w/w cellulose, 25% w/w hemicellulose, and 25% w/w lignin. Due to its abundant availability, the bagasse can serve as an ideal substrate for microbial processes for the production of value-added products such as protein-enriched animal feed, enzymes, amino acids, organic acids, and compounds of pharmaceutical importance.

The utilization of organic and agricultural residues such as bagasse for energy production is considered an important part in any strategy to achieve renewable energy goals and to reduce waste disposal and environmental pollution. For energy production, bagasse can be burned as a raw product or in the form of briquettes. Currently, most sugar cane bagasse is burned in boilers to produce steam which is utilized in factories and to power turbines for the production of electricity (cogeneration).

The combustion of sugar cane bagasse yields ash (bottom ash and fly ash) that contains high amounts of organic matter (charcoal and sugar cane bagasse debris) and inorganic components (on the order of 65% w/w).

One of the significant applications of bagasse is the production of protein-enriched cattle feed and enzymes. Bagasse could also be used for the production of industrially important enzymes and biofuel.

Bagasse Briquettes

Bagasse is the fibrous residue remaining after sugarcane or sorghum stalks, for example, are crushed to extract their juice. It is currently used as a renewable resource in the manufacture of pulp and paper products and building materials. However, surplus bagasse presents a disposal problem for many sugar factories. Briquetting technology offers a way to reduce the surplus amount of bagasse.

A briquette (also spelled briquet) is a compressed block of (typically) combustible material (such as charcoal, sawdust, and wood chips) used for fuel. In some cases, the briquettes may be used for transportation before further processing. A piston press is used to create solid briquettes for a wide array of purposes. Screw extrusion is used to compact biomass into loose, homogeneous briquettes that are substituted for coal in cofiring. This technology creates a toroidal (doughnut-like) briquette.

The briquetting process involves the following steps: (i) size reduction in which the bagasse is chopped, rolling, or hammered, (ii) drying in which moisture is removed by open air drying or by using forced, heated air in a large rotating drum, (iii) carbonization in which the bagasse is combusted in a limited supply of oxygen in a buried pit or trench until it carbonizes into charcoal, (iv) feedstock preparation in which the carbonized bagasse is mixed with a binder such as clay or molasses, (v) compaction and extrusion in which the material is passed through a machine-operated or manually-operated extruder to form rolls of charcoal, (vi) drying in which the rolls are air-dried for 1 to 3 days, causing them to break into chunks, and (vii) packaging in which the briquettes are made ready for sales.

Baghouse

The baghouse (also known as a baghouse filter, bag filter, fabric filter, or fabric collector) uses filtration to separate dust particulates from particle-laden gases. They are one of the most efficient and cost-effective types of dust collectors available and can achieve a collection efficiency of more than 99% for fine particulates. A baghouse can be engineered for almost any dust producing application under almost any set of circumstances. In the cleaning process, particle-laden gases enter the baghouse and pass through a series of fabric bags that act as filters. The bags can be made of woven or felted cotton, synthetic, or glass-fiber material in either a tube or envelope shape.

The high efficiency of these collectors is due to the dust cake formed on the surfaces of the bags. The fabric primarily provides a surface on which dust particulates collect through the following mechanisms which are (i) inertial collection in which dust particles strike the fibers placed perpendicular to the gas-flow direction instead of changing direction with the gas stream, (ii) interception in which particles that do not cross the fluid streamlines come in contact with fibers because of the fiber size, and (iii) electrostatic forces in which the presence of an electrostatic charge on the particles and the filter can increase dust capture. A combination of these mechanisms results in formation of the dust cake on the filter, which eventually increases the resistance to gas flow. The filter must be cleaned periodically.

Baghouses come in design classifications based on the manner by which the bags are cleaned: (i) the pulse jet system, which uses high-pressure air directed down into the clean side of a filter bag in order to remove the dust cake from the surface of the media, (ii) the shaker style system, which involves shaking the bags in order to mechanically release the dust cake, and (iii) the reverse air system in which the bags are collapsed in order to mechanically shear the dust cake from the bag surface.

In mechanical-shaker baghouses, tubular filter bags are fastened onto a cell plate at the bottom of the baghouse and suspended from horizontal beams at the top. The contaminate gas streams enters the bottom of the baghouse and passes through the filter, and the dust collects on the inside surface of the bags. Cleaning a mechanical-shaker baghouse is accomplished by shaking the top horizontal bar from which the bags are suspended. Vibration produced by a motor-driven shaft and cam creates waves in the bags to shake off the dust cake.

In reverse-air baghouses, the bags are fastened onto a cell plate at the bottom of the baghouse and suspended from an adjustable hanger frame at the top. Dirty gas flow normally enters the baghouse and passes through the bag from

the inside, and the dust collects on the inside of the bags. In reverse-jet baghouses, individual bags are supported by a metal cage, which is fastened onto a cell plate at the top of the baghouse. Dirty gas enters from the bottom of the baghouse and flows from outside to inside the bags. The metal cage prevents collapse of the bag. Bags are cleaned by a short burst of compressed air injected through a common manifold over a row of bags. The compressed air is accelerated by a venturi nozzle mounted at the reverse-jet baghouse top of the bag. Since the duration of the compressed-air burst is short (0.1 seconds), it acts as a rapidly moving air bubble, traveling through the entire length of the bag and causing the bag surfaces to flex. This flexing of the bags breaks the dust cake, and the dislodged dust falls into a storage hopper below.

Cartridge collectors are another commonly used type of dust collector. Unlike baghouse collectors, in which the filtering media is woven or felt bags, this type of collector employs perforated metal cartridges that contain a pleated, nonwoven filtering media. Due to its pleated design, the total filtering surface area is greater than in a conventional bag of the same diameter, resulting in reduced air-to-media ratio, pressure drop, and overall collector size.

See also: Baghouse Filter.

Baghouse Filter

Baghouse fabric filters are generally used where higher removal efficiency is required for particles smaller than approximately 10 microns. Thus, the filter is an air pollution control device and dust collector that removes particulates or gas released from commercial processes. A large number of bag-shaped filters would be needed to clean large gas flows. In general, all of the filters would be enclosed in the same structure (a *baghouse*) and would share input and output gas manifolds.

As a gas stream passes through the baghouse, dust is removed by one or more of the following physical phenomena: intersection, impingement, diffusion, gravitational settling, or electrostatic attraction. The initial filtration creates a layer of dust on the bag fabric. This layer is primarily responsible for this method's high removal efficiency; the filter cloth serves mainly as a support structure.

The efficiency of a baghouse filter depends on the particle size distribution, the particle density and chemistry, and moisture. Under most conditions, a well-designed and well-operated baghouse will achieve a removal efficiency of at least 99% for particles as small as 1 micron. In the renewable energy industry, baghouse filters are likely to be used for dust removal from crushers, screens, transfer points, and storage bins.

Fabric life may be substantially shortened in the presence of high acid or alkaline atmospheres, especially at elevated temperatures; also, the maximum operating temperature is limited to 285°C (550°F), unless special fabrics are used.

Barrel

The standard oil barrel of 42 US gallons is used in the United States as a measure of crude oil and other crude oil products. The 42 US gallon size of barrel as a unit of measure is largely confined to the American oil industry, since other sizes of barrel were used by other industries in the United States, and nearly all other countries use the metric system. Many oil-producing countries that did not have the technical expertise to develop their own domestic oil industry standards use the American oil barrel because their oil industries were founded by US oil companies.

Outside of the United States, oil is commonly measured in cubic meters (m³) or in tonnes (1 tonne = 2,204.6 lbs), with tonnes more often being used by European oil companies. International companies listed on American stock exchanges tend to convert their oil production volumes to barrels for global reporting purposes, and those listed on European exchanges tend to convert their production to tonnes.

The wooden oil barrel of the late 1800s is different from the modern day 55-gal steel drum (known as the 44-gal drum in Britain and the 200-L drum in Australia). The 42-US gallon oil barrel is a unit of measure, and is no longer used to transport crude oil – most crude oil is moved in pipelines or oil tankers.

The barrel of oil equivalent (BOE) is a unit of energy based on the approximate energy released by burning one barrel (42 US gallons) of crude oil. The Internal Revenue Service of the United States defines the barrel of oil equivalent as equal to 5.8×10^6 Btu. A barrel of oil equivalent is approximately 6,000 ft³ of typical natural gas.

Other conversion data are the BBOe, (also BBOE), or billion barrel of oil equivalent, representing 10⁹ (US billion) barrels of oil, used to measure crude oil reserves, and million barrels per day, MMbd (or MMBD), used to measure daily production and consumption. Also used is the Mtoe (not *middle toe* but *millions of tonnes of oil equivalent*), a metric measurement equivalent to approximately 0.006841 billion barrels of oil equivalent.

The barrel of oil equivalent is used by oil and gas companies in their annual financial statements as a way of combining oil reserves and natural gas reserves as well as production into a single measure.

See also: Barrel of Oil Equivalent.

Barrel of Oil Equivalent

A barrel of oil equivalent (BOE or a barrel of crude oil equivalent, BCOE) is used to summarize the amount of energy that is equivalent to the amount of energy found in a barrel of crude oil. Thus, a barrel of crude oil is a liquid measure equal to 42 US gallons (35 Imperial gallons or 158.9873 L). The BOE is the amount of energy contained in a barrel of crude oil; a barrel of crude oil is approximately (because of the difference in crude oil properties and character) equivalent to 5.8 million Btu. Also, approximately 7.2 barrels of oil are equivalent to one ton of oil. A BOE is approximately roughly 6,000 ft³ of natural gas.

A commonly used multiple of the BOE is the kilo-barrel of oil equivalent (kboe or kBOE), which is 1,000 times larger. Other common multiples are the billion BOE, representing 10⁹ barrels of oil, used to measure crude oil reserves, and million barrels per day (MMbd or MMBD), used to measure daily production and consumption. Also used is the million tons of oil equivalent (Mtoe) which is a metric measurement equivalent to approximately 0.006841 billion barrels of crude oil equivalent.

The BOE is used by oil and gas companies in their financial statements as a way of combining crude oil reserves and natural gas reserves and production into a single measure.

Basic Nitrogen

Nitrogen in liquid fuels (renewable fuels are included here) may be classified arbitrarily as basic and non-basic (Table B-1). The basic nitrogen compounds, which are composed mainly of pyridine-type homologs and occur throughout the boiling ranges of organic compounds, which are usually of the pyrrole, indole, and carbazole types, have a decided tendency to exist in the higher boiling fractions and crude oil residua and in liquids from alternative energy sources such as biomass and organic waste.

Organic nitrogen-containing compounds have many important roles in nature (hence, also in biomass) and display an enormous structural diversity, in which the nitrogen atoms can form part of simple functional groups or complex heterocyclic systems. The basic nitrogen compounds also have varying degrees of substitution and oxidation. The most noteworthy of these naturally occurring molecules are proteins, and most vitamins and hormones. Furthermore, nitrogen compounds in liquids produced from a variety of sources (including biomass and organic waste) can have a deleterious effect on any catalysts used to upgrade the liquid.

Basic nitrogen compounds with a relatively low molecular weight can be extracted with dilute mineral acids; equally strong bases of higher molecular weight remain unextracted because of unfavorable partitioning between the oil and aqueous phases. A method has been developed in which the nitrogen compounds are classified as basic or non-basic, depending on whether they can be titrated with perchloric acid in a 50:50 solution of glacial acetic acid and benzene.

Table B-1 Non-basic and basic nitrogen types.

Nonbasic		
Pyrrole	C_4H_5N	
Indole	C_8H_7N	
Carbazole	$C_{12}H_9N$	
Benzo(a)carbazole	$C_{16}H_{11}N$	
Basic		
Pyridine	C_5H_5N	
Quinoline	C_9H_7N	
Indoline	C_8H_9N	
Benzo(f)quinoline	$C_{13}H_9N$	

Nitrogen compounds extractable with dilute mineral acids from renewable fuels typically consist of alkyl pyridine derivatives, alkyl quinoline derivatives, and alkyl isoquinoline derivatives carrying alkyl substituents, as well as pyridine derivatives in which the substituent was a cyclopentyl or cyclohexyl group. The compounds that cannot be extracted with dilute mineral acids contain the greater part of the nitrogen in crude oil and are generally of the carbazole, indole, and pyrrole types.

Thus, the presence of the various types of nitrogen compounds in any feedstock must be monitored because they can critically affect aquatic ecosystems, especially their high levels can cause eutrophication under certain conditions. Ammonia, organic species, nitrate derivatives ($-NO_3$), and nitrite derivatives ($-NO_2$) can be present in wastewaters. In general, ammonia and organic species are the most common in raw water. Ammonia is the initial product of the decay of nitrogenous organic wastes, its presence being an indication of such wastes. Typically, the nitrate content in waters is low but can rise to appreciable levels in wastewater from agricultural activities as a result of soil fertilization. Also, nitrite derivatives are present in low concentration since these are rapidly oxidized to nitrates, while nitrite derivatives can be found in wastewaters from the microbiological reduction of nitrate or the oxidation of ammonia.

See also: Waste, Waste Disposal.

Basic Sediment and Water

The basic sediment and water (often referred to in a shortened form, such as BS&W, BSW) is the material which collects in the bottom of storage tanks and is usually composed of oil, water, and foreign matter, also called bottoms or bottom settlings. The material is also known as bottoms, bottom sediment, bottom settlings, sediment, and water.

The particulate matter is known as sediment or mud. The water content can vary greatly from fuel to fuel (conventional or alternate). The bulk of the water and sediment is usually separated as soon as possible after production to minimize the quantity that needs to be transported and/or transferred to subsequent processing units. Further, the residual content of these unwanted impurities is measured as bottom sediment and water (BS&W, ASTM D4007).

Thus, basic sediment and water are both a technical specification of certain impurities in any fuel and the method for measuring it. In many raw fuels (including fuels produced from biomass), the crude oil will contain some amount

of water and suspended solid from the starting material. The particulate matter and the water content can vary greatly from feedstock to feedstock and from process to process. The bulk of the water and sediment is usually separated at the earliest possible convenience to minimize the quantity that needs to be transported further as well as any adverse effects on the process and process equipment.

Upon production of a fuel from a renewable source, the fuel typically passes through facilities that allow gas and water to separate from the crude and solids to settle out. These facilities may comprise a simple gathering tank or a series of specialized separation vessels, and may involve the addition of chemicals to the crude to aid in the separation of various contaminants from the crude oil and natural gas.

The BS&W test has been used to determine composition of the fuel from many sources and should be tested frequently to ensure it meets the prescribed quality requirements. There are two tests conducted, a bottom sediment and water test (BS&W) and a visual test. The BS&W test is done at the beginning, mid-point, and end of the fuel production train. Visual tests are conducted every fifteen minutes during the evolution. The visual criteria is simply that the fuel be *clear and bright* and the test is a quick and easy check of the fuel quality.

See also: Refining.

Batch-Type Processes

A batch process is usually performed over and over, and batch processes are a sub-class of sequential processes. Batch process refers to a process that involves a sequence of steps followed in a specific order. Also, batch processes generate a product but the sequential processes need not necessarily generate a product. Thus, batch processing is a technique for automating and processing multiple portions of a feedstock. More generally, industrial processes can be divided into two categories of production which are (i) continuous processes and (ii) batch processes.

Continuous processes are designed to run at steady state, and to maximize the efficiency of these processes, it is necessary to keep the plant in the operating range under disturbances. The optimization task required to operate such processes is usually performed to achieve disturbance rejection, designing controllers to reach and maintain set-point effectively, and keeping the down time to a minimum. Since the operating range is generally very narrow, the system dynamics can often be approximated by linear dynamics.

Batch processes have a finite operating time, rather than a continuous operation. The control objective in batch processing is not to reach steady state, but to reach some desired objective by the end of the batch. This can involve movement through a very wide operating range, and non-linearity in the system can be strong. Batch optimization focuses on maximizing the performance objective by finding the corresponding input variable and state variable trajectories. Since batch production is usually of low volume, high value production, optimization of its operation is critical to make the process viable.

The most common type of process for acid gas removal is the batch-type process, and many involve a chemical process in which the acid gas reacts chemically with the cleaning agent, usually a metal oxide. These processes are not merely physical separation processes in which the acid gas is removed by a physical phenomenon, such as adsorption. Thus, the batch-type processes have the common requirement that the process be operated as a batch system where, at the end of the cycle, the chemical agent must be changed or regenerated in order to continue treating.

Batch processes are limited to removing small amounts of sulfur from fuels, especially when the flow rates of the gas streams and/or there are small concentrations of hydrogen sulfide. These processes include (i) the iron sponge process, (ii) the ChemSweet process, (iii) the SulphaCheck process, (iv) the SulphaTreat process, (v) the zinc oxide process, and (vi) the molecular sieve process.

Baumé Gravity

Baumé gravity is a unit of measurement of specific gravity used in the chemical industry for aqueous caustic soda and aqueous acid. Two arbitrary scales are employed, one for liquids lighter than water and the other for liquids heavier than water. This scale is also used to describe the density of acid solutions (Table B-2).

Table B-2 Explanation of the baumé gravity scale.

For liquids heavier (More dense) than water	For liquids lighter (less dense) than water
0° Bé is the distance the hydrometer sinks in pure water.	0° Bé is the distance the hydrometer sinks in a solution that is 10% w/w sodium chloride (salt, NaCl)
15° Bé is distance the hydrometer sinks in a solution that is 15% w/w sodium chloride (salt, NaCl)	10° Bé is the distance the hydrometer sinks in ° pure water.
To convert from °Bé to specific gravity at 60 F: specific gravity = $145/(145 - ^\circ\text{Bé})$	To convert from Bé to specific gravity at 60 F: specific gravity = $140/(130 + ^\circ\text{Bé})$

Before standardization using specific gravity at the time of World War II, the Baumé scale was generally used in industrial chemistry and pharmacology for the measurement of density of liquids. Currently, the Baumé scale is still used in various industries such as sugar beet processing and in the starch industry and the density of liquid product produced from these two sources could well be presented in degrees Baumé.

Bauxite

Bauxite is an amorphous sedimentary rock that is the chief commercial ore of aluminum. It consists largely of hydrated alumina with variable proportions of iron oxides. In addition, bauxite is the main source of aluminum and gallium. The ore consists mostly of the aluminum minerals gibbsite [$\text{Al}(\text{OH})_3$], boehmite [$\gamma\text{-AlO}(\text{OH})$], and diaspore [$\alpha\text{-AlO}(\text{OH})$] that are mixed with the two iron oxides: goethite [$\text{FeO}(\text{OH})$] and hematite (Fe_2O_3) as well as the aluminum clay minerals kaolinite [$\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})$] and small amounts of anatase (TiO_2), and ilmenite (FeTiO_3 or $\text{FeO} \cdot \text{TiO}_2$).

The principal aluminum hydroxide minerals found in varying proportions with bauxites are gibbsite and the polymorphs boehmite and diaspore. Bauxite ores are typically classified according to their intended commercial applications such as an abrasive, a cement constituent, an industrial chemical, and a refractory material. The bulk of world bauxite production (approximately 85%) is used as feed for the manufacture of alumina (Al_2O_3) via a wet chemical caustic leach method (the Bayer process). Subsequently, the majority of the resulting alumina produced from this refining process is in turn employed as the feedstock for the production of aluminum metal by the electrolytic reduction of alumina in a molten bath of natural or synthetic cryolite (Na_3AlF_6).

Bauxite is useful in the alternate energy industry insofar as it can be used as a catalyst to convert many different sulfur compounds, in particular mercaptan derivatives (RSH), into hydrogen sulfide (H_2S), which is subsequently removed by a lye treatment (caustic treatment, alkali treatment).

To prepare aluminum oxide, bauxite is heated in pressure vessels with sodium hydroxide solution at 150–200°C through which aluminum is dissolved as aluminate (Bayer process). After separation of ferruginous residue (red mud) by filtering, pure gibbsite is precipitated when the liquor is cooled and seeded with fine-grained aluminum hydroxide. Gibbsite is converted into aluminum oxide by heating. This is molten at approx. 1,000°C (1,830°F) by addition of cryolite as a flux and reduced to metallic aluminum by a highly energy-consuming electrolytic process (Hall-Héroult process).

During the processing of bauxite to alumina (Al_2O_3) in the Bayer process, gallium accumulates in the sodium hydroxide liquor from which it can be extracted by a variety of methods. Achievable extraction efficiencies critically depend on the original concentration in the bauxite feedstock.

Bauxite ores are industrially important for the supply of aluminum metal, and these ores represent the only raw material used in the production of alumina on a commercial scale. Gallium is a common by-product of the process, and both aluminum and gallium may also be considered as a possible future resource for rare earth elements that find use in renewable energy technologies.

See also: Bauxite Treating Process.

Bauxite Treating Process

Bauxite ore is a mixture of hydrated aluminum oxide derivatives and compounds of other elements such as iron. The aluminum compounds in the bauxite may be present as gibbsite [$\text{Al}(\text{OH})_3$], boehmite [or böhmite, $\gamma\text{-AlO}(\text{OH})$], or diasporite [$\alpha\text{-AlO}(\text{OH})$]. The different forms of the aluminum component and the impurities dictate the extraction conditions. Aluminum oxides and hydroxides are amphoteric – having both acidic and basic character.

In the Bayer process, a mixture of the bauxite ore and a sodium hydroxide solution is heated in a pressure vessel at a temperature of 150 to 200°C (300 to 390°F), causing the aluminum to be dissolved as sodium aluminate. After separation of the residue by filtering, gibbsite is precipitated when the liquid is cooled and then seeded with fine-grained aluminum hydroxide crystals from previous extractions.

The extraction process converts the aluminum oxide in the ore to soluble sodium aluminate (NaAlO_2), and at the same time, silica is dissolved to form sodium silicate (Na_2SiO_3):

The other components of the bauxite ore do not dissolve.

Lime may be added to precipitate the silica as calcium silicate (CaSiO_3). The undissolved waste (bauxite tailings) after the aluminum compounds are extracted contains iron oxides, silica, lime (CaO), titania (TiO_2), and some unreacted alumina.

See also: Bauxite.

Beavon Process

The Beavon sulfur removal process for the cleanup of Claus plant tail gas is a two-step process in which the sulfur contaminants are first catalytically hydrolyzed and/or hydrogenated to hydrogen sulfide and the hydrogen sulfide is then converted to elemental sulfur and recovered in a Stretford process unit.

In the process, which consists of two stages, the sulfur-containing compounds, such as hydrogen sulfide (H_2S), sulfur dioxide (SO_2), carbonyl sulfide (COS), and carbon disulfide (CS_2), are converted to sulfur in over 99.9% efficiency. In the first stage, the various sulfur compounds are either hydrogenated or hydrolyzed to give hydrogen sulfide, while in the second stage, the hydrogen sulfide is oxidized using the Stretford process to give good-quality elemental sulfur. This process can also be utilized in synthetic natural gas plants, natural gas processing, and other similar applications.

Benchmark Crude Oil

A benchmark crude oil is a crude oil that is used as the standard crude oil against which the properties of the (liquid) source of any fuel (even a renewable fuel) can be measured or compared. When evaluating the price of any crude oil, it is important to compare the crude oil against an appropriate benchmark crude oil.

The price of crude oil means the spot price of either West Texas Intermediate crude oil as traded on the New York Mercantile Exchange (NYMEX) for delivery in Cushing, Oklahoma, or of Brent crude as traded on the Intercontinental Exchange (ICE, into which the International Petroleum Exchange has been incorporated) for delivery at Sullom Voe. The price of a barrel of oil is highly dependent on both its grade, determined by factors such as its specific gravity or API gravity and sulfur content, as well as location. The vast majority of oil is not traded on an exchange but on an over-the-counter basis, typically with reference to a marker crude oil grade that is typically quoted via pricing. Other important benchmark crude oils include Dubai, Tapis, and the OPEC basket.

For the purposes of pricing, crude oil is generally classified based on the API gravity and sulfur content. For example, light crude oil has low density, low viscosity (there are no exact numbers assigned to this, because the classification is more practical and theoretical), and low sulfur content, making it easier to transport and refine and, therefore, more expensive to purchase. Sweet crude oil has a sulfur content less than 0.5% by weight and is usually (but not always) light crude oil, making it much easier to refine in a way that would meet environmental standards in developed countries - and making it more expensive.

A light crude oil is generally one with an API gravity of less than approximately 40 – for example, Brent crude oil has an API gravity on the order of 38 to 39°. Sweet crude is preferable to sour crude oil because it is also (like light crude) more suited to the production of the most valuable refined products. On the other hand, heavy crude oil has high density, high viscosity, and high sulfur content making it more difficult to transport and refine and cheaper to purchase. Typically, sour crude oil has a sulfur content above 0.5% by weight and is usually *heavy crude oil*, making it cheaper to purchase but more expensive to refine.

Heavy crude oil will typically have an API gravity of 20 or less - the higher the API gravity, the lower the density. Heavy crude oil is harder to handle (it is too thick to pump easily through pipelines unless diluted with light crude) and is more expensive to refine to produce the most valuable crude oil products such as naphtha (gasoline), kerosene, diesel fuel, and aviation fuel.

Because there are so many different varieties and grades of crude oil, buyers and sellers have found it easier to refer to a limited number of reference, or benchmark, crude oils. Other varieties are then priced at a discount or premium, according to their quality. Thus, crude oil is priced in terms of regional blends, each with different characteristics. Of these, certain blends are followed by traders, as they most reflect the overall value of oil, and therefore affect the way different blends are priced. These are essentially like a Consumer Price Index for different types of oil. Approximately 160 different types of crude are traded around the world; the four primary benchmarks, of which these are priced internationally are (i) Brent blend crude oil, (ii) West Texas intermediate (WTI) crude oil, (iii) Dubai crude oil, and (iv) the OPEC Basket crude oil.

The Brent crude oil blend is based on the prices of Brent crude, which is a light, sweet crude oil and is actually a combination of crude oil from 15 different oil fields in the Brent and Ninian systems located in the North Sea. The API gravity is 38.3° (making it a “light” crude oil, but not quite as “light” as West Texas Intermediate crude oil), while it contains approximately 0.37% by weight sulfur (making it a *sweet* crude oil, but again slightly less *sweet* than West Texas Intermediate crude oil). The Brent blend is ideal for making gasoline and middle distillates, both of which are consumed in large quantities in Northwest Europe, where Brent blend crude oil is typically refined. However, if the arbitrage between Brent and other crude oils, including WTI, is favorable for export, Brent has been known to be refined in the United States (typically the East Coast or the Gulf Coast) or the Mediterranean region. Brent blend, like West Texas Intermediate crude oil, production is also on the decline, but it remains the major benchmark for other crude oils in Europe or Africa.

Beta Decay

Beta decay (β -decay) is a type of radioactive in which a beta particle (a fast energetic electron or positron) is emitted from an atomic nucleus which transforms the original nuclide to an isobar of that nuclide.

By definition, an isobar is an atom (nuclide) of different chemical elements that have the same number of nucleons. Correspondingly, an isobar differs in atomic number (or the number of protons) but has the same mass number. An example of a series of isobars is ^{40}S , ^{40}Cl , ^{40}Ar , ^{40}K , and ^{40}Ca .

Thus, the beta decay of a neutron transforms it into a proton by the emission of an electron accompanied by an antineutrino or, conversely, a proton is converted into a neutron by the emission of a positron with a neutrino in the positron emission reaction. Neither the beta particle nor its associated (anti-)neutrino exist within the nucleus prior to beta decay, but are created in the decay process. By this process, unstable atoms obtain a more stable ratio of protons to neutrons. The probability of a nuclide decaying due to beta and other forms of decay is determined by the nuclear binding energy.

Thus, the two types of beta decay are known as *beta minus* and *beta plus*. In the former [beta minus decay (β^- decay)], a neutron is converted to a proton, and the process creates an electron and an electron antineutrino, while

in beta plus decay (β^+ decay, also known as positron emission), a proton is converted to a neutron and the process creates a positron and an electron neutrino.

An example of electron emission (β^- decay) is the decay of carbon-14 (^{14}C) into nitrogen-14 (^{14}N) with a half-life on the order of 5,730 years:

In this form of decay, the original element becomes a new chemical element (nuclear transmutation) and the new element has an unchanged mass number (A) but atomic number (Z) that is increased by one. As in all nuclear decays, the decaying element (in this case $^{14}_6\text{C}$) is the *parent nuclide*, while the resulting element (in this case $^{14}_7\text{N}$) is known as the *daughter nuclide*.

Another example is the decay of hydrogen-3 (^3H , tritium) into helium-3 (^3He) with a half-life on the order of 12.3 years:

An example of positron emission (β^+ decay) is the decay of magnesium-23 (^{23}Mg) into sodium-23 (^{23}Na) with a half-life on the order of 11.3 seconds:

Beta+ decay (β^+ decay) also results in nuclear transmutation, with the resulting element having an atomic number that is decreased by one.

See also: Alpha Decay, Alpha Particle, Nuclear Energy.

Beta Particle

A beta particle is emitted from the nucleus of a radioactive atom with a wide range of energies up to some maximum value. When a beta particle is emitted that is below the maximum value, the neutrino carries away the rest of the energy.

Like the alpha particles, beta particles, like alpha particles, lose energy by ionization and excitation, but because of their small mass (1/7,300 of an alpha particle) and lower charge (1/2 of that of an alpha particle), the interactions take place at less frequent intervals. Therefore, the beta particles do not produce as many ion pairs per centimeter of path as alpha particles, and thus, have a greater range in matter which depends on the energy of the particle and the composition of the material.

Bioalcohol

Biologically produced alcohols, such as ethanol, propanol and butanol, are produced by the action of microorganisms and enzymes through the fermentation of starches, sugars, or cellulose. Alcohol fuels are produced by fermentation of sugars derived from corn, molasses, sugar beets, sugar cane, wheat, as well as potato and fruit waste.

However, as an example, there is no difference in properties between ethyl alcohol produced in a petrochemical facility and ethanol from biomass; it is merely the use of the prefix “bio” to define the origin of the alcohol. However, in some cases, ethanol ($\text{C}_2\text{H}_5\text{OH}$) that is derived from crude oil should not be considered safe for consumption as this alcohol contains approximately 5% v/v methanol (CH_3OH) and may cause blindness or death. This mixture may also not be purified by simple distillation, as it forms an azeotropic mixture.

Bioalcohols are a useful type of liquid fuel because they combust rapidly and are often cheap to produce. However, their acceptance is hampered by the fact that their production often requires as much or even more fossil fuel than they replaced since they are typically not primary sources of energy; however, they are a convenient way to store the energy for transportation.

Biomethanol

Methanol (the simplest alcohol, CH_3OH) is the lowest molecular weight and simplest alcohol, produced from natural gas (methane). It is also called methyl alcohol or wood alcohol, the latter because it was formerly produced from the distillation of wood. Currently, the majority of the methanol produced is manufactured from natural gas, a non-renewable fossil fuel, and modern methanol is also produced in a catalytic industrial process directly from carbon monoxide, carbon dioxide, and hydrogen. However, methanol can also be produced from biomass (as biomethanol) using similar chemical processes.

Bioethanol

Ethanol, also known as grain alcohol or ethyl alcohol, is most commonly used in alcoholic beverages. The ethanol production methods used are enzyme digestion (to release sugars from stored starches), fermentation of the sugars, distillation, and drying. Ethanol is produced mostly from carbohydrates produced in starch and sugar crops such as corn or sugar cane. The distillation process requires significant energy input for heat (often unsustainable natural gas, but cellulosic biomass such as bagasse, the waste left after sugar cane is pressed to extract its juice, can also be used more sustainably). Ethanol can be used as a fuel for vehicles in its pure form, but it is usually used as a gasoline additive to increase octane and improve vehicle emissions.

Two types of grain ethanol production are currently available in the United States, dry milling and wet milling, with the latter predominating among large-scale producers.

Corn dry milling is the most common type of ethanol production in the United States. In the dry grind process, the entire corn kernel is first ground into flour and the starch in the flour is converted to ethanol via fermentation. The other products are carbon dioxide (used in the carbonated beverage industry) and an animal feed called distillers' dried grain with soluble matter.

Corn wet milling is the process of separating the corn kernel into starch, protein, germ, and fiber in an aqueous medium prior to fermentation. The primary products of wet milling include starch and starch-derived products (e.g., high fructose corn syrup and ethanol), corn oil, and corn gluten.

Ethanol can also be produced from other forms of biomass that do not fall under the nomenclature of food crops. One set of production processes is applicable to what is known as cellulosic biomass, including fast-growing fuel crops, agricultural waste such as bagasse and corn stover, and forest and wood processing waste, while a second set of techniques can make use of practically any form of inexpensive biomass including the cellulosic sort as well as the black liquor produced by paper mills, animal wastes, and some types of landfill wastes.

Ethanol can be readily produced by fermentation of simple sugars that are converted from starch crops. Feedstocks for such fermentation ethanol include corn, barley, potato, rice, and wheat. This type of ethanol may be called grain ethanol, whereas ethanol produced from cellulose biomass such as trees and grasses is called bioethanol or biomass ethanol." Both grain ethanol and bioethanol are produced via biochemical processes, while chemical ethanol is synthesized by chemical synthesis routes that do not involve fermentation.

Cellulosic biofuels, such as cellulosic ethanol, began to be produced in commercial-scale plants in 2013. These fuels are made from cellulose-containing organic material. Cellulose forms the primary structural component of green plants and is by far the most abundant organic (carbon-containing) compound on Earth. The primary cell wall of green plants is made primarily of cellulose; the secondary wall contains cellulose with variable amounts of lignin. Lignin and cellulose, considered together, are termed lignocellulose, which (as wood) is the most common biopolymer on Earth. Cellulosic biomass, derived from non-food sources, such as trees and grasses, is also being developed as a feedstock for ethanol production. Even dry ethanol has roughly one-third lower energy content per unit of volume compared to gasoline, so larger (and therefore heavier) fuel tanks are required to travel the same distance, or more fuel stops are required.

Ethanol may also be used as a fuel, most often in combination with gasoline. For the most part, it is used in a 9:1 ratio of gasoline to ethanol to reduce the negative environmental effects of gasoline. There is increasing interest in the

use of a blend of 85% fuel ethanol blended with 15% gasoline. This fuel blend, called E85, has a higher fuel octane than premium gasoline, allowing in properly optimized engine increases in both power and fuel economy over gasoline.

Biopropanol

Propanol (propyl alcohol, C_3H_7OH) is the next member of the alcohol series followed by butanol (butyl alcohol, C_4H_9OH). Both alcohols may be used as a fuel with the normal combustion engine. The advantages of propanol and butanol are the high octane rating (over 100) and high energy content, only approximately 10% lower than gasoline, and subsequently more energy-dense than methanol and ethanol. The major disadvantage of propanol and butanol as fuels for the internal combustion engine is the relative high flashpoint of these alcohols.

Biobutanol

Butanol can be produced from biomass (as biobutanol) as well as fossil fuels, but biobutanol and crude oil-derived butanol (sometimes referred to as petro-butanol) have the same chemical properties. Butanol may be used as a fuel in an internal combustion engine. Because its longer hydrocarbon chain causes it to be fairly non-polar, it is more similar to gasoline than it is to ethanol. Butanol has been demonstrated to work in vehicles designed for use with gasoline without modification, and is thus often claimed to provide a direct replacement for gasoline (in a similar way to biodiesel in diesel engines). Biobutanol has the advantage in combustion engines in that its energy density is closer to gasoline than the simpler alcohols (while still retaining over 25% higher octane rating); however, biobutanol is currently more difficult to produce than ethanol or methanol.

Biocatalysts

A biocatalyst is a catalyst (such as, for example, an enzyme) that is of biological origin. Thus, biocatalysis is the use of natural catalysts, such as protein enzymes, to perform chemical transformations on organic compounds. Both enzymes that have been more or less isolated and enzymes still residing inside living cells are employed for this task. More than one hundred years ago, biocatalysis was employed to achieve chemical transformations on non-natural man-made organic compounds, and the last 30 years have seen a substantial increase in the application of biocatalysis to produce fine chemicals, especially for the pharmaceutical industry.

Biocatalysts are living (biological) systems that increase the rate of chemical reactions. In biocatalytic processes, natural catalysts, such as enzymes, perform chemical transformations of organic compounds. In fact, enzymes that have been isolated as separate molecular entities as well as enzymes still remain inside living cells are employed as catalysts that can catalyze novel small molecule transformations that may be difficult or impossible using classical synthetic organic chemistry. In addition, enzymes are environmentally benign insofar as they can be completely degraded in the environment.

Biocatalysts do not operate by different scientific principles from organic catalysts. The existence of a multitude of enzyme models including oligopeptide or polypeptide catalysts proves that all enzyme action can be explained by rational chemical and physical principles. However, enzymes can create unusual and superior reaction conditions such as extremely low pK_a values or a high positive potential for a redox metal ion. Enzymes have increasingly been found to catalyze almost any reaction of organic chemistry. Moreover, the notion that biocatalysts are slow catalysts is false and optimized syntheses not only produce high selectivity or total turnover numbers but also satisfactory-to-high yields of products.

See also: Enzymes.

Biochar

Biochar is organic matter that has undergone combustion under low to no oxygen conditions (such as during pyrolysis) resulting in a recalcitrant, high carbon material specifically for use as a soil amendment. Recently, fervent interest in the production of biochar to address issues of fertility, water-holding capacity, remediation, climate change mitigation, etc., led to a much greater understanding of the complexities of this potential amendment in altering soil

biological, chemical, and physical properties. Rather than assume the benefit of any biochar created from any feedstock added to any soil ecosystem, concepts of matching appropriate feedstock and pyrolysis condition to soil type to achieve specific goals associated with remediation, increasing yields, decreasing greenhouse gas emission, and/or climate change mitigation emerged.

This porous sponge-like property of biochar makes it useful for many things such as the production of activated carbon filters used to purify water. Industrial production of biochar employs pyrolysis, a means of combustion without much air or oxygen and that is more efficient in that it produces little ash.

The production of biochar is a sustainable option for waste management since the char contains 50% of the original carbon which is highly recalcitrant in nature; therefore, its production helps in carbon sequestration by locking the carbon present in the plant biomass. The elemental composition and structural configuration of biochar is strongly correlated with temperature, heating rate, and residence time maintained during its production. Along with the biochar, some amount of bio-oil and gases are also produced which can be used for generation of energy and various chemicals.

Soil pH and electrical conductivity (EC) increase in soil incorporated with biochar which may be due to the presence of ash residue that is dominated by carbonates of alkali and alkaline earth metals, and some amount of silica, heavy metals, and organic and inorganic nitrogen. With its large surface area, biochar helps in increasing water holding capacity, cation exchange capacity (CEC), and microbial activity (act as its habitat) and also reduces leaching of nutrient by providing nutrient binding sites. This reduces the total fertilizer requirement of biochar-amended soil and thereby reduces environmental pollution caused by leaching of inorganic fertilizer. It also plays a vital role in increasing crop productivity. Apart from improving soil quality, biochar provides various other benefits such as (i) mitigation of greenhouse gases (such as methane, CH_4 , nitrous oxide, N_2O , and carbon dioxide, CO_2), (ii) a decrease in the dissipation rate of herbicide in soil, and (iii) wastewater treatment. Due to large availability of biomass resources, biochar can be a prime product in many countries.

See also: Pyrolysis.

Biochemical Conversion

Biochemical conversion is the use of (i) fermentation or (ii) anaerobic digestion to produce fuels and chemicals from organic sources. In the general sense, fermentation refers to any chemical change of organic material that is accompanied by effervescence, normally without the participation of oxygen. The important differences between fermentation and anaerobic digestion are the nature of the product produced and the character of the biological contribution. Fermentation produces a liquid product in the presence of enzymes, while anaerobic digestion yields a gaseous product as a result of the metabolic activity of bacteria (Table B-3).

Ethanol is the principal product of the fermentation processes appropriate to biomass conversion, although other alcohols, as well as organic acids, ketones, and aldehydes, may be produced either as main products or as by-products. Anaerobic digestion is the decomposition of any organic material by the metabolic action of bacteria without the participation of atmospheric oxygen. Methane and carbon dioxide are the main products of the decomposition. The source of the oxygen in the carbon dioxide is the combined oxygen in the organic molecules and in the water.

Table B-3 Biomass conversion processes.

Process	Biomass feedstock	Scale*	Product
Combustion	Wood, municipal solid waste, grasses, crop residue	Small, large	Heat, steam, electricity
Gasification	Wood, municipal solid waste (grasses, crop residue)	Large	Low-heat content gas, synthesis gas ethanol
Pyrolysis	Wood, sewage sludge	Large	Medium-heat content gas tar
Fermentation	Grain and sugar crops	Small, large	Ethanol

*Small implies domestic or farm application; large is industrial-scale processing of up to 1,000 t/d of biomass.

Bacterial digestion is in effect accomplished by enzymes. Further, certain bacteria produce acids and alcohols as the principal degradation products. In some cases, it is not clear whether the degradation proceeds as a result of bacterial metabolism, or whether it can be achieved by non-growing cells. Nevertheless, the distinction between the two processes is convenient for presentation purposes, and should not cause confusion in classifying the important biochemical processes currently in contention.

Biomass fermentation to produce ethanol is similar to glycolysis (the fermentation that occurs in muscle tissue and converts glucose to lactic acid with the release of energy), but the use of different enzymes results in different end products.

Biochemical Oxygen Demand

Biochemical oxygen demand (BOD) is a chemical procedure for determining the rate of uptake of dissolved oxygen by the rate biological organisms in a body of water use up oxygen. It is a chemical measure of the power of an effluent to deoxygenate water. The test is widely used as an indication of the quality of water. The biochemical oxygen demand can be used as a gauge of the effectiveness of wastewater treatment plants. There are two recognized methods for the measurement of biochemical oxygen demand which are (i) the dilution method and (ii) the manometric method.

In the dilution method, a small amount of microorganism seed is added to each sample being tested. This seed is typically generated by diluting activated sludge with de-ionized water. The test is carried out by diluting the sample with oxygen saturated de-ionized water, inoculating it with a fixed aliquot of seed, measuring the dissolved oxygen, and then sealing the sample to prevent further oxygen dissolving in. The sample is kept at 20°C in the dark to prevent photosynthesis (and thereby the addition of oxygen) for five days, and the dissolved oxygen is measured again. The difference between the final dissolved oxygen and initial dissolved oxygen is the biochemical oxygen demand. The apparent biochemical oxygen demand for the control is subtracted from the control result to provide the corrected value.

In the manometric method, the sample is kept in a sealed container fitted with a pressure sensor. A substance that absorbs carbon dioxide (typically lithium hydroxide) is added in the container above the sample level. The sample is stored in conditions identical to the dilution method. Oxygen is consumed, and dioxide is released. The total amount of gas, and thus the pressure, decreases because carbon dioxide is absorbed. From the drop of pressure, the sensor electronics computes and displays the consumed quantity of oxygen.

Biochemicals

Biochemicals, as opposed to petrochemicals, are in the context of this encyclopedia, chemicals produced from biomass.

The production of chemicals from biomass, a renewable feedstock, is highly desirable in replacing petrochemicals to make biorefineries more economical. The best approach to compete with fossil-based refineries is the upgradation of biomass in integrated biorefineries. The integrated biorefineries employed various biomass feedstocks and conversion technologies to produce biofuels and bio-based chemicals. Bio-based chemicals can help to replace a large fraction of industrial chemicals and materials from fossil resources. Biomass-derived chemicals, such as 5-hydroxymethylfurfural (5-HMF), levulinic acid, furfurals, sugar alcohols, lactic acid, succinic acid, and phenols, are considered platform chemicals. These platform chemicals can be further used for the production of a variety of important chemicals on an industrial scale. However, current industrial production relies on relatively old and inefficient strategies and low production yields, which have decreased their competitiveness with fossil-based alternatives.

Biomass feedstocks, such as agricultural residues and wood chips, constitute an inexpensive renewable resource for commercial large-scale biorefineries, as these waste products are widely available and can sequester carbon. The target chemicals include alcohol derivatives, organic acid derivatives such as formic acid and levulinic acid, and furan derivatives such as 5-hydroxymethylfurfural (5-HMF) and furfural derivatives. These chemicals can further be converted to a range of derivatives that have potential applications in biofuels, polymers, and solvent industries.

Due to these differences in their chemical composition and structure, cellulose, hemicellulose, and lignin have different chemical reactivities. In addition to the complex nature of bio-resources, the inert chemical structure and compositional ratio of carbon, hydrogen, and oxygen in molecules in biomass present difficulties in the chemo-catalytic conversion of biomass to fuels and chemicals. Therefore, besides using the natural lignocellulosic biomass as a reactant, researchers often use model compounds for conversion process studies. In addition, the development of highly active and selective catalysts for the chemo-selective catalytic conversion of lignocellulosic biomass to desired products remains a daunting challenge.

The development of processes and technologies to convert lignocellulosic biomass to fuels and value-added chemicals remains a significant challenge. In this context, the major difficulty in producing a high yield of target chemicals and fuels is the complex chemical composition of lignocellulosic biomass feedstocks. Structurally, cellulose contains anhydrous glucose units and hemicellulose consists of different C5 sugar monomers. On the other hand, lignin is a complex, three-dimensional, and cross-linked biopolymer having phenylpropane units with relatively hydrophobic and aromatic properties. Due to these differences in their chemical composition and structure, cellulose, hemicellulose, and lignin have different chemical reactivities. In addition to the complex nature of bio-resources, the inert chemical structure and compositional ratio of carbon, hydrogen, and oxygen in molecules in biomass present difficulties in the chemo-catalytic conversion of biomass to fuels and chemicals.

A variety of methods can be employed to obtain different product portfolios of bulk chemicals, fuels, and materials. Biotechnology-based conversion processes can be used to ferment the biomass carbohydrate content into sugars that can then be further processed. For instance, the fermentation path to lactic acid shows promise as a route to bio-degradable plastics and has been demonstrated commercially. An alternative is to employ thermochemical conversion processes which use pyrolysis or gasification of biomass to produce a hydrogen-rich synthesis gas. This synthesis gas can then be used in a wide range of chemical processes.

While the concept of exploiting the wide range of chemicals from plants may appear novel, the published literature shows that large numbers of metabolites have already been identified and characterized from a wide variety of plant species. For example, over 37,000 different potential and unexploited materials can be identified. These have a wide range of chemical, physical, and biological properties and include phenolics, nitrogen containing compounds, and terpenes (terpenoids). The variety of molecular compounds is vast. For example, in the terpene group, there are six sub-groupings of molecules with a large number of applications including use in anti-cancer drugs.

Extraction procedures can have a major impact on the availability of these chemicals, and, to ensure optimal exploitation, some of the well-established extraction procedures may need to be revised. For example, in winter rapeseed, the harvested seed is crushed and rapeseed oil extracted mechanically. The residual meal is then treated with hexane to extract the remaining oil, before being used as feed, primarily for ruminants. Rapeseed oil components have numerous applications including use in bio-diesel, and specialty chemicals.

However, innovative oil-extraction procedures could allow greater exploitation of protein-based metabolites in the rapeseed, which can comprise 25% or more of the rapeseed mass. Research from studies, such as the EC-funded Enhance project, has demonstrated that this separation would allow products to be produced for numerous applications (see diagram) with base cellulose material and some other metabolites remaining in the residual meal.

Biochemicals - Production

Basic knowledge of the mechanisms of common reactions such as dehydration, hydrogenation, and hydrodeoxygenation involved in biomass upgradation processes is discussed in the following section.

Dehydration

Dehydration is a reaction in which a water molecule is removed from the substrate, mainly alcohol, forming an alkene or other unsaturated product depending on the substrate. The reaction is commonly catalyzed by Lewis or Brønsted acids, as the hydroxyl group is a poor leaving group. Dehydration in the presence of a Brønsted acid catalyst occurs by first protonating the hydroxyl group, as the protonated hydroxyl group ($\text{R-H}_2\text{O}^+$) is a better leaving group

than the hydroxyl group. As a result, the catalyst is eliminated as water. Simultaneously, a carbon-carbon double bond ($C=C$) is formed in the carbon skeleton of the substrate, as per Zaitsev's rule.

In Lewis acid-catalyzed reactions, however, the reaction proceeds through the bonding of Lewis acid to the lone electron pair of hydrogen-oxygen. The electrophile nature of the Lewis acid lowers the electron density in the alcohol carbon-oxygen bond, which results in the cleavage of the alcohol carbon-oxygen ($C-O$) bond and the formation of alkene and Lewis acid hydroxide specie. The Lewis acid hydroxide reacts with the released β -proton, forming water and the original catalyst species.

Due to the abundances of hydroxyl groups in a wide variety of natural resources, dehydration reactions are the most common and important ways to valorize biomass. As a result, different dehydration products can be obtained from biomass, and are used as high-value chemicals.

Hydrogenation

Hydrogenation is a reaction in which hydrogen atoms are added to an unsaturated compound to reduce the double and triple bonds. Molecular hydrogen (H_2 , gaseous) and other compounds (transfer hydrogenation) can be used as a hydrogen source in the reaction. However, the addition of hydrogen does not take place without a catalyst; therefore, the reaction is catalyzed by homogeneous and heterogeneous catalysts to increase the feasibility of reactions at the laboratory and industrial scales within short time durations. Most commonly, heterogeneous systems with solid metal hydrogenation catalysts and molecular hydrogen are used as catalysts for biomass conversion reactions.

Hydrogenation with a heterogeneous solid metal catalyst and hydrogen follows the Horiuti-Polanyi mechanism. First, the hydrogen molecule is chemisorbed on the surface of the catalyst, followed by the scission of a hydrogen-hydrogen ($H-H$) bond producing two adsorbed hydrogen atoms. Next, the unsaturated reactant is adsorbed on the catalyst. The opening of a double bond through chemisorption follows this. The hydrogen atoms are transferred to the chemisorbed reactant on the surface of the catalyst in a stepwise manner of which the first hydrogen transfer is reversible. The second hydrogen transfer forms the reduced reaction product, and then it is desorbed from the surface of the catalyst, thus completing the reaction cycle.

Hydrogenation is the most fundamental reaction in chemistry. Nature produces many different unsaturated products including carbon-carbon double ($C=C$) bonds, in carbonyl groups, in the structural aldoses and ketoses of cellulose and hemicellulose. The hydrogenation of these biomass-derived monosaccharides in lignocellulosic biomass produces sugar alcohols. For example, hydrogenation of glucose and xylose, the main components in lignocellulosic biomass, produces sorbitol and xylitol, respectively. In addition, the dehydration products can be further upgraded through hydrogenation. These hydrogenation products can be used as solvents, monomers, and biofuels. The synthesis and uses of hydrogenation of biomass-derived substrates will be covered in more detail.

Hydrodeoxygenation

Hydrodeoxygenation (HDO) is a hydrogenolytic reaction in which the removal of the oxygen atom from the reactant occurs in the presence of hydrogen (H_2). The removal of oxygen-containing functionalities can occur through direct hydrogenolysis ($C-O$ bond cleaved with hydrogen), dehydration ($C-O$ bond cleaved through the removal of water), decarbonylation (removal of carbon monoxide), and decarboxylation (removal of carbon dioxide). The most common hydrodeoxygenation pathways depend on the oxygen moieties. Hydrodeoxygenation also needs selective catalysts to facilitate the formation of the desired reaction products. Catalysts typically contain noble metals as the hydrogenation catalyst, as well as Brønsted or Lewis acidic sites for cleavage of the carbon-oxygen bonds. The hydrodeoxygenation mechanisms of different oxygen functionalities depend on the reaction conditions and catalysts used.

In the case of biomass or biomass-derived substrates, hydrodeoxygenation reactions are used to reduce high oxygen content. Typically, these hydrodeoxygenation reactions require a high temperature and high pressure, possibly resulting in the formation of product mixtures through cleavage of carbon-carbon bonds and carbon skeleton rearrangements. In this context, new catalytic systems need to be developed to remove the oxygen-containing functionalities.

Production from Lignin

Lignin is the key constituent of the lignocellulosic biomass and responsible for the structural and mechanical integrity of plants. Lignin is a polymer with wide variability in structure. Its components depend on the biomass source

and are most often combined with cellulose and hemicelluloses. It is considered the least susceptible to chemical and biotransformation techniques. Therefore, lignin often becomes a low-value waste product of biomass processing technologies, such as in the conventional paper and pulp industry and in the modern bioethanol-fuel-production industry. Therefore, lignin valorization in relation to energy, chemical, and biotechnological application is creating considerable interest to researchers.

Structurally, lignin is a three-dimensional amorphous phenolic polymer that consists of monomers such as phenylpropane unit, C3C6 including p-coumaryl, sinapyl, and coniferyl alcohol. It contains β -O-4 (40% to 60%), biphenyl (3.5% to 25%), α -O-4 (3% to 5%), and β -5 (4% to 10%) linkages. The different structural and chemical properties of lignin lead to the production of a wide variety of aromatic chemicals. Therefore, lignin was observed as the major aromatic source of the bio-based economy. Dimethyl sulfide, vanillin, and dimethyl sulfoxides are the chemicals, manufactured from lignin on a large scale. Several researchers have summarized the applications of lignin as a renewable resource, such as emulsifier, bio-dispersant, polyurethane foams, wood panel products, resins, automotive brakes, and precursors for the synthesis of thermoplastic materials in the industry. In addition, the production of aromatics from depolymerization of lignin is considered as the most promising process for the sustainable utilization of lignin. Aromatics can be derived from monomeric C6 fragments from depolymerized lignin. The maximum theoretical obtainable yield of benzene, toluene, and xylene (BTX) from lignin is approximately 36 to 42%, as lignin contains 60% to 65% carbon in C6 aromatic rings. The main challenge in producing aromatics is to selectively deoxygenate and dealkylate the C6 aromatic structure (typically with hydrogen) without hydrogenating C6 aromatic rings. The difficulty in the valorization of lignin originates from its complex polymeric structure, which differs from one lignin to another depending on the botanical origin and the pretreatment used for its separation from carbohydrates (cellulose and hemicellulose).

The catalytic pathways, including base-catalyzed depolymerization, pyrolysis, and Lewis acid-catalyzed solvolysis, have been investigated and studied for the conversion of lignin to valuable compounds. Low product yields and severe treatment conditions, as well as complex product mixtures, have been major drawbacks for lignin conversion. However, lignin's aromatic nature and its versatile functional groups suggest that it can be a valuable source of chemicals, particularly monomeric phenolics. Hydrothermal liquefaction of lignin in the presence of water as the solvent leads to the production of bulk aromatic compounds. Bio-oil obtained after lignin decomposition contains monomeric phenols and oligomeric polyphenols. The monomeric phenols are valuable chemicals; however, the oligomeric polyphenols that existed in bio-oils were volatile and viscous, which makes them more difficult for conversion into useful products. As a result, the conversion of lignin to monomers instead of oligomers is highly desirable.

The thermochemical conversions such as catalytic fast pyrolysis and microwave pyrolysis were commonly used processes in the presence of effective catalysts to enhance reactions, including cracking, decarbonylation, deoxygenation, and decarboxylation. Recently, several studies have been reported for lignin depolymerization to obtain monomeric phenols. The monomers of phenols such as alkylated phenol and guaiacol have found applications as intermediates for the production of polymers, antioxidants, resins, medicines, and pesticides. The preparation of phenolic resins such as phenol-formaldehyde using phenolic-rich pyrolysis oils is well known.

Phenolic compounds are obtained from lignocellulosic biomass after treatment with alkali. A large number of different methods have been discussed, but the processes reported are complex, low yielding, cost-ineffective, and energy inefficient. The most challenging aspect of the production of chemicals from lignin-derived monomeric phenols using catalytic hydrotreatment is the synthesis of catalysts that can perform deoxygenation without saturating the aromatic rings in the phenol deoxygenation processes. This will help to decrease the hydrogen consumption. For this process, mainly conventional metal sulfide, metal oxide, transition metal phosphide, metal carbides, and bi-metallic catalysts were used. Bi-metallic catalysts are found to be more suitable than monometallic catalysts for deoxygenation of phenols.

Ni-based catalysts were used for lignin hydrogenation/hydrogenolysis in 1940. Ni catalysts supported on carbon and magnesium oxide were found to be active for C-O bond cleavage of model compounds as well as selectively hydrogenating the aryl ether C-O bonds of β -O-4 without disturbing the arenes. The alcohol solvents were used as a hydrogen donor for the hydrogenolysis of lignin. The platinum group metals (palladium, Pd, platinum, Pt, ruthenium, Ru, rhodium, Rh, and iridium, Ir) bear higher intrinsic activity than Ni catalysts and hence were widely reported for hydrogenolysis of lignin. Zn in Pd-based catalysts was found to be far more effective than the Pd/C catalyst and Zn-based catalysts were effective for the cleavage of β -O-4 bonds in lignin model compounds.

Oxidative depolymerization of lignin leads to the production of polyfunctional aromatic compounds. These compounds include aromatic aldehydes and carboxylic acids, such as 4-hydroxybenzaldehyde, vanillin, muconic acid, and syringaldehyde, which are good alternatives to crude oil-based chemicals. The depolymerization of lignin in 1-ethyl-3-methyl-imidazolium trifluoromethanesulfonate with nitrate catalysts yielded pure 2,6-dimethoxy-1,4-benzoquinone. The catalytic systems for lignin oxidation involve organometallic catalysts, metal-free organometallic catalysts, acid or base catalysts, metal salt catalysts, photocatalytic, and electrocatalytic oxidation. Methyltrioxorhenium (MTO) in combination with H_2O_2 catalyzed lignin oxidation reactions is the most promising. This catalytic system leads to extensive oxidation on the aliphatic side-chain and aromatic-ring cleavages.

Lignin-Derived Polymers

After the depolymerization and production of aromatic compounds from lignin, the consequent processes do not require much advancement. The mature technologies already exist for the transformations of aromatic compounds into commodity monomers and polymers. The commodity polymers that can be derived from lignin are polyethylene terephthalate (PET), Kevlar, polystyrene, polyanilines, and unsaturated polyesters. The alternatives to fossil-based aromatic polymers could be accomplished by the full valorization of lignin. The synthesis of bio-based PET can be realized by the preparation of ethylene glycol (EG) and p-terephthalic acid from renewable biomass. Bio-based p-xylene can be used as the raw material for p-terephthalic acid to produce a 100% plant-based PET. Sulfur-free lignin derivatives have been widely used as a raw material for wood panel products, polyurethane foams, automotive brakes, biodispersants, and epoxy resins for printed board circuits. Cornstalk-derived bio-oils were used to synthesize phenol-formaldehyde resins.

An integrated biorefinery approach will optimize the utilization of renewable biomass for the production of bio-energy, biofuels, and bio-derived chemicals for the short- and long-term sustainability. For an integrated biorefinery, the concept of usage of platform intermediates as precursors to different products by chemo-catalytic routes will be of highest importance. This will offer the refinery the necessary adaptability to product demand. This review summarizes the production of platform chemicals from lignocellulosic biomass components. The three main components of lignocellulosic biomass, cellulose, hemicellulose, and lignin are valuable precursors for numerous chemicals having valuable applications. The target chemicals include furan derivatives, such as 5-hydroxymethylfurfural (5-HMF), 2,5-dimethylfuran (2,5-DMF), sugar alcohols and organic acids, such as levulinic acid, lactic acid, succinic acid, and aromatic chemicals. These chemicals can be further converted to a range of derivatives that have potential applications in the polymer and solvent industries. The chemo-catalytic routes were found to be most promising ones for the conversion of biomass feedstocks to these high-value chemicals.

Production from Sugars

Cellulose and hemicellulose are the polymers of C6 and C5 sugar units that are linked by ether bonds. Cellulose consists of D-glucose units connected by β -1-4 linkages and extensive hydrogen bonding which makes the hydrolysis process difficult. Acid and enzymatic hydrolysis are commonly used to liberate the monosaccharide glucose units. Hemicellulose contains C5-sugars, such as xylose, galactose, mannose, and arabinose. The dehydration of C5 sugars can yield furfural, which is a platform chemical that has applications ranging from solvents to resin and fuel additives. The large-scale synthesis of organic chemicals and chemicals based on furan from sugars is an important alternative to crude oil-based energy resources.

Hydroxymethylfurfural

Hydroxymethylfurfural (5-HMF), also 5-(hydroxymethyl)furfural (5-HMF) is the most important platform chemical from renewable feedstock for the next-generation plastic and biofuel production. The derivatives such as levulinic acid, 2,5-bis(hydroxymethyl)furan (2,5-BHF), 2,5-dimethylfuran (2,5-DMF), and 2,5-diformylfuran (2,5-DFF) were synthesized from 5-HMF. Other derivatives are 1,6-hexanediol, 5-hydroxymethyl-2-furan carboxylic acid (HMFCA), 2,5-furfuryldiamine, 2,5-furfuryldiisocyanate, and 5-hydroxymethyl furfuryliden ester. These derivatives have found applications as precursors for the synthesis of materials such as polyesters, polyamides, and polyurethane. The synthesized polymeric materials exhibit good properties. Polyurethane demonstrates high resistance to thermal treatments; photoreactive polyesters have been used for ink formulations, and Kevlar-like polyamides exhibit liquid crystal behavior.

The formation of furan-based derivatives from the hydroxymethylfurfural by catalytic oxidation and hydrogenation processes is reported in Figure 8. The chemicals obtained include 2,5-diformylfuran (2,5-DFF), 2,5-dimethylfuran (2,5-DMF), 2,5-furan dicarboxylic acid (2,5-FDCA), and 2,5-bis(hydroxymethyl)furan (2,5-BHF). 2,5-DFF is produced by the selective and partial oxidation of 5-HMF. It is used in the synthesis of fungicides, drugs, and polymeric materials. Several promising catalytic routes for 2,5-DFF production are reported in the literature. The complete transformation of 5-HMF with a 90% yield of 2,5-DFF was achieved with a vanadium oxide titanium oxide (V_2O_5/TiO_2) catalyst in the presence of air and toluene or methyl isobutyl ketone (MIBK) as the solvent.

Furfural

Furfural is also considered a key chemical produced in lignocellulosic biomass refineries. Hemicellulose, which contains a large amount of C5 sugars xylose and arabinose, can serve as a raw material for the production of furfural. This industrial chemical is mainly obtained from xylose by dehydration. Furfural has been used as a foundry sand linker in the refining of lubricating oil. The use of furfural as an intermediate for the production of chemicals such as furan, furfuryl alcohol, and tetrahydrofuran (THF) has been reported. Reviews have been published on the chemistry of furfural.

Commercially, furfural is produced by the acid-catalyzed transformation of pentosan sugars; C5 polysaccharides are first hydrolyzed by H_2SO_4 to monosaccharides (mainly xylose), which are subsequently dehydrated to furfural. Furfural is then recovered from the liquid phase by steam stripping to avoid further degradation and purified by double distillation. Several reports on the conversion of raw biomass into C5 sugars and furfural using mineral acid and solid acid catalysts were published. The use of these catalysts makes the reaction system more corrosive, which increases the capital costs of the processes. The use of ionic liquids for furfural manufacture has been widely discussed. An ionic liquid plays a role as an acidic catalyst for pentose dehydration in aqueous media, eventually in the presence of organic solvents. These can also act as additives for improving the furfural yields in the reaction media comprised of xylose or xylan, organic solvent, and acidic catalysts. Ionic liquids can also serve as a reaction medium for furfural manufacturing from pentoses, higher saccharides made up of pentoses, or pentosans.

The important chemical obtained from furfural is furfuryl alcohol (FA), and approximately 65% of the overall furfural produced is consumed for the production of FA. FA is currently manufactured industrially by hydrogenation of furfural in the gas or liquid phase over Cu-Cr catalysts. However, chromium in these catalysts causes serious environmental problems because of its high toxicity. Therefore, current studies are focused on exploring more environmentally acceptable catalysts that could selectively hydrogenate the carbonyl group while preserving the C=C bonds. The hydrogenation of furfural over Raney Ni modified by impregnation with heteropolyacid (HPA) salts, such as $Cu_3/2PMo_{12}O_{40}$, that produced a 96.5% yield of furfuryl alcohol was reported. Recently, novel catalyst synthesis methods such as atomic layer deposition (ALD) and encapsulation in metal organic frameworks have been reported.

2-Methylfuran (2-MF) is another industrial chemical that can be synthesized from furfural. 2-MF is also a biofuel component. Another one, tetrahydrofurfuryl alcohol (THFA), is typically produced from furfural via furfuryl alcohol as an intermediate. The hydrogenolysis of tetrahydrofurfuryl alcohol to 1, 5-pentanediol (1, 5-Ped), a promising biofuel component, was disclosed using Rh-MoOx/SiO₂ and Rh-ReOx/SiO₂ catalysts with 85% and 86% yields, respectively. Furfuryl alcohol and THFA are widely used as green solvents for the synthesis of resins. These can also be used as raw materials for the synthesis of fuels and fuel additives. Cyclopentanone (CPO) is another C5 chemical that can be synthesized from furfural. CPO can be widely used in the production of fuels and polymeric materials. Mainly, Cu-based catalysts are used for the transformation of furfural to cyclopentanone.

The decarboxylation of furfural leads to the production of furan. The hydrogenation of furan produced tetrahydrofuran (THF). Furan and THF are also important industrial chemicals. Furfural can be decarboxylated in both gas- and liquid-phase reactions. Supported noble metal catalysts (Pd, Pt, Rh) and mixed metal oxides, such as Zn-Fe, Zn-Cr, Zn-Cr, and Mn were investigated. The decarboxylation has been found to be most efficient with Pd-based catalysts at a high pressure of hydrogen and a high and reaction temperature. These rigorous reaction conditions result in catalyst deactivation. Additionally, the noble metals used are expensive and limited in abundance. Therefore, alternate active and selective catalysts need to be explored.

The oxidation of furfural can also lead to the production of C4 chemicals such as maleic anhydride (MAN), maleic acid (MA), and succinic acid (SA). The use of vanadium oxide-based catalysts has been studied for gas-phase

oxidation of furfural to maleic anhydride with oxygen. The use of oxidants such as oxygen and hydrogen peroxide (H_2O_2) was also discussed for the oxidation of furfural. The combination of copper nitrates with phosphomolybdic acids selectively converts furfural to maleic acid with a 49.2% yield or maleic anhydride with a 54% yield in a liquid medium using oxygen as an oxidant.

Sugar Alcohols

Lignocellulosic-based sugar alcohols, such as sorbitol, mannitol, xylitol, and erythritol, are potential fuels and chemicals widely used for polymer, food, and pharmaceutical applications. These are extensively used as moisturizers, sweeteners, softeners, texturizers, and food for diabetic patients. Currently, sorbitol and mannitol can be synthesized through hydrogenation of fructose and glucose. Xylitol and erythritol can be prepared by the conversion of xylose and glucose, respectively. Many catalytic systems and methods have been reported for the conversion of cellulose into sorbitol and mannitol via hydrolysis followed by hydrogenation. The use of noble metal-based catalysts Pt/SBA-15 and Ru-PTA/MIL-100(Cr) for the conversion of glucose and cellulose into sorbitol, respectively, were reported. However, cheaper non-metal catalysts (supported on TiO_2 , Al_2O_3 , SiO_2 , MgO, ZnO, and ZrO_2) have been found to be effective in converting cellulose into sorbitol and mannitol.

Industrially, xylitol is synthesized by the hydrogenation of pure xylose, while xylose can be obtained through acidic hydrolysis of hemicellulose biomass (corncocks and hardwoods). The first report on the synthesis of xylitol through the hydrogenation of xylose over a Raney Ni catalyst was carried out in a three-phase slurry reactor. The acid-transition metal or bi-functional catalysts were used for the hydrolysis and hydrogenation of cellulose to sugar alcohols in the presence of hydrogen pressure.

Erythritol is a C4-sugar alcohol, mainly found in food ingredients. It occurs as a metabolite or storage compound in fruits, such as grapes, pears, seaweed, and fungi. Pentose sugars (arabinose and xylose) are the precursors for producing C4-sugar alcohols. The most efficient route for the synthesis of erythritol from pentose sugars is selective cleavage of a carbon-carbon bond. The production of erythritol and threitol is mostly carried out at a high temperature range of 200 to 240°C (390 to 465°F) with a pressure of hydrogen pressure of in alkaline conditions. Very few findings relate to the selective bond cleavage to produce erythritol.

Succinic Acid

Succinic acid is one of the 12 high-value bio-based chemicals investigated by Werpy and Peterson as a compound that has the potential to improve the profitability and productivity of biorefineries. Conventionally, succinic acid is produced from maleic acid using Pd/C heterogeneous metal catalysts. Other methods reported for succinic acid production are oxidation of 1,4-butanediol with nitric acid; the carbonylation of ethylene glycol, acetylene, and dioxane; hydrogenation of fumaric acid in the presence of Ru catalyst; and the condensation of acetonitrile to produce butanedinitrile, which can be subsequently hydrolyzed to succinic acid.

Lactic Acid

Lactic acid (2-hydroxypropanoic acid) is an important chemical. It is an alternative for producing alkyl lactates, propylene glycol, propylene oxide, acrylic acid, and poly (lactic acid). Lactic acid has applications in food, pharmaceuticals, and cosmetics. In particular, the biopolymers from lactic acid have created a strong interest. Conventionally, lactic acid is produced via fermentation from carbohydrates.

Lactic acid can be made from different reagents such as lignocellulosic materials, cellulose, carbohydrates, sugars, trioses, glycolaldehyde, and glycerol. The production of lactic acid involves complex reactions of several types of transformations such as aldol condensation, retro-aldol condensation, dehydration, and 1,2-hydride shifts.

Several homogeneous and heterogeneous catalysts have been reported for the production of lactic acid from biomass. The catalysts such as alkali metal ions, tin chloride, tin dioxide (SnO_2), acidic resins, zeolites, metal-modified zeolites, mesoporous materials, tungstated alumina, mixed-oxides, and carbon-silica hybrid materials have been reported in the literature. The use of Rh/C, Ru/C, Ir/C, Ir/ CaCO_3 , and Pt/C catalysts for the transformation of glycerol to lactic acid was discussed. Typically, the highest yield of lactic acid has been achieved in the presence of an inert gas and alkaline medium (CaCO_3). An alkaline platinum-calcium carbonate (Pt/CaCO_3) catalyst has been shown to be an efficient catalyst for glycerol transformation to lactic acid, with 54% selectivity for lactic acid at 45%

conversion in the presence of borate esters at 200°C (390°F). The Rh/Al₂O₃ catalyst also gives high selectivity for lactic acid, i.e., 69% in the presence of borate derivatives.

Chemicals such as pyruvic acid, acrylic acid, 2,3-pentanedione, polylactic acid (PLA), lactic acid esters, and 1,2-propanediol (1,2-PDO) can be synthesized from lactic acid. The polylactic acid can be synthesized by two ways: direct polycondensation of LA and ring-opening polymerization of the lactide monomer (cyclic). The direct polycondensation of lactic acid is a difficult process because of the strong equilibrium between polylactic acid, water, and lactide that limits the synthesis of high molecular weight products. The most commonly used process is using the lactide intermediate. The lactide intermediate was polymerized via a homogeneously catalyzed ring-opening polymerization (absence of water), which produces two lactoyl units in the growing chain. This process suffers from racemization. Consequently, when commercial L-lactic acid was used, a 5% to 12% yield of undesired product (meso-lactide) was produced. The properties of polylactic acid depend mainly on the stereo-composition of the feed used. Therefore, stereo-pure L,L-lactide is used to obtain stereo-pure poly-L-lactic acid. As a result, improvements in catalysts, process parameters, and configuration have been reported.

Catalytic dehydration of lactic acid leads to acrylic acid, while propanoic and pyruvic acids were obtained by lactic acid reduction and dehydrogenation, respectively. 2,3-pentanedione can be produced by condensation and acetaldehyde by either decarbonylation or decarboxylation. The lactic acid conversion to acetaldehyde was investigated on silica-supported heteropolyacid with an 83% yield.

Hydrogenation of lactic acid to 1,2-propanediol was performed in both the liquid as well as the vapor phase using Ru/C and Cu/SiO₂ catalysts, respectively. The direct hydrogenolysis of lactic acid seems an attractive option, but deactivation of catalyst makes the process undesirable. The catalyst deactivation occurs as a result of the polymerization of lactic acid and formation of the side-products, propionic acid. Therefore, to avoid this problem, carboxylic acids are usually converted into more readily reducible esters.

In summary, the catalytic conversions of sugars to commodity chemicals are widely discussed, but the industrial applications are limited. Therefore, further research for the improvements of the catalytic conversion and selectivity are still required for achieving the goal of integrated biorefineries. The areas that need attention are the search for novel reaction media to use efficient catalysts for the biomass conversion processes and the extraction/purification steps to isolate the chemicals with high yield and purity.

Bioconversion

Bioconversion is the use of biological agents to carry out a structured deconstruction of lignocellulose components. This platform combines process elements of pretreatment with enzymatic hydrolysis to release carbohydrates and lignin from wood.

The first step is a pretreatment stage which is based on existing pulping processes; however, traditional pulping parameters are defined by resulting paper properties and desired yields, while optimum bioconversion pretreatment is defined by the accessibility of the resulting pulp to enzymatic hydrolysis. This function of this step is to optimize the biomass feedstock for further processing and is designed to expose cellulose and hemicellulose for subsequent enzymatic hydrolysis, increasing the surface area of the substrate for enzymatic action to take place. The lignin is either softened or removed, and individual cellulosic fibers are released creating pulp.

In order to improve the ability of the pretreatment stage to optimize biomass for enzymatic hydrolysis, a number of non-traditional pulping techniques have been suggested and include (i) water-based systems, such as steam-explosion pulping, (ii) acid treatment using concentrated or dilute sulfuric acid, (iii) alkali treatment using recirculated ammonia, and (iv) organic solvent pulping systems using acetic acid or ethanol. As with traditional pulping, pretreatment tends to work best with a homogenous batch of wood chips, but the pretreatment option may have to be selected according to the type of lignocellulosic feedstock.

Once pretreated, the cellulose and hemicellulose components of wood can be hydrolyzed (in this option) using enzymes to facilitate bioconversion of the wood. Enzymatic hydrolysis of lignocellulose materials uses cellulase enzymes to break down the cellulosic microfibril structure into the various carbohydrate components.

The enzymatic hydrolysis step may be completely separate from the other stages of the bioconversion process, or it may be combined with the fermentation of carbohydrate intermediates to end-products. Separate hydrolysis and fermentation (SHF) stages may offer this option more flexibility insofar as process adaptation to feedstock type and product slate is available. Simultaneous saccharification and fermentation (SSF) have been found to be highly effective in the production of specific end products, such as bioethanol.

The benefit of bioconversion is that it provides a range of intermediate products, including glucose, galactose, mannose, xylose, and arabinose, which can be relatively easily processed into value-added bioproducts. The process also generates a quantity of lignin or lignin components; depending upon the pretreatment, lignin components may be found in the hydrolysate after enzymatic hydrolysis, or in the wash from the pretreatment stage. The chemical characteristics of the lignin are therefore heavily influenced by the type of pretreatment that is employed. Finally, a relatively small amount of extractives may be retrieved from the process. These extractives are highly variable depending upon the feedstock employed, but may include resins, terpenes, or fatty acids.

Once hydrolyzed, six-carbon sugars can be fermented to ethanol using yeast-based processes. Five-carbon sugars, however, are more difficult to ferment and lack the efficiency of six-carbon sugar conversion. Bacterial fermentation under aerobic and anaerobic conditions is also an option to expand the variety of other products.

A large number of options on the various aspects of bioconversion are available. The environmental performance of bioethanol, including air quality (NO_x, PM, SO_x, etc.) is also well documented as are the mass-balance and energy-balance of the bioconversion process and economic analyses.

See also: Biochemical Conversion.

Bioconversion Platform

The bioconversion platform is an industrial option (as might be used in a biorefinery) for producing fuels from biomass using biochemical reactions and/or biochemical agents. For example, fermentation or anaerobic digestion to produce fuels and chemicals from organic sources is a bioconversion platform. The bioconversion platform therefore has the ability to serve as the basis for wood-based biorefining operations, generating value-added bioproducts as well as fuel and energy for the forest sector.

The bioconversion platform typically uses a combination of physical or chemical pretreatment and enzymatic hydrolysis to convert lignocellulose into its component monomers. Once liberated, the carbohydrate components of wood may be processed into a number of chemical and fuel products.

Bioconversion technology is leading the way to new chemical products from the lignocellulose-based biorefinery, including bioethanol, lactic acid and polylactide, propanediol, and succinic acid. Other chemical products can be used to create consumer products such as bioplastics, or as platform chemicals in a number of industrial applications. The development of better ways to separate lignin from the lignocelluloses matrix during bioconversion has created the possibility of developing value-added lignin-based products as well.

The bioconversion platform uses biological agents to carry out a structured deconstruction of lignocellulose components and combines process elements of pretreatment with enzymatic hydrolysis to release carbohydrates and lignin from the wood. The first step is a pretreatment stage which must optimize the biomass feedstock for further processing. In the bioconversion platform, this step must be designed to expose cellulose and hemicellulose for subsequent enzymatic hydrolysis, increasing the surface area of the substrate for enzymatic action to take place.

Bioconversion proceeds at lower temperatures and lower reaction rates and can offer high selectivity for products. Bioethanol production is a biochemical conversion technology used to produce energy from biomass. For ethanol production, biochemical conversion researchers have focused on a process model of dilute acid hydrolysis of hemicelluloses followed by enzymatic hydrolysis of cellulose. Biodiesel production is a biochemical conversion technology used to produce energy from oilseed crops.

As in traditional pulping, lignin is either softened or removed, and individual cellulosic fibers are released creating pulp. While bioconversion pretreatment is based on existing pulping processes, however, traditional pulping parameters are defined by resulting paper properties and desired yields, while optimum bioconversion pretreatment is defined by the accessibility of the resulting pulp to enzymatic hydrolysis.

Once pretreated, the cellulose and hemicellulose components of wood can be hydrolyzed. The majority of the commercial hydrolysis programs use enzymes to facilitate fast, efficient, and economic bioconversion of the wood. Enzymatic hydrolysis of lignocellulose materials uses cellulase enzymes most commonly produced by fungi such as *Trichoderma*, *Penicillium*, and *Aspergillus*. A cocktail of cellulase enzymes is required in order to break down the cellulosic microfibril structure into its carbohydrate components in an efficient manner, unlike the bioconversion of starch, which has a simpler chemical structure. The enzymatic hydrolysis step may be completely separate from the other stages of the bioconversion process, or it may be combined with the fermentation of carbohydrate intermediates to end-products.

Separate hydrolysis and fermentation (SHF) offers the platform more flexibility, and makes it easier in theory to alter the process for different end products; however a separate process requires additional engineering and will cost more to build and operate. Simultaneous saccharification and fermentation (SSF) has been found to be highly effective in the production of specific end products, such as bioethanol.

Separation techniques are being developed to isolate the base components of cellulose, hemicellulose, and lignin in order to facilitate industrial processing of these components. Sometimes, the most effective isolation may be carried out by combining correct pretreatments with enzymatic hydrolysis.

The advantage of the bioconversion platform is that it provides a range of intermediate products, including glucose, galactose, mannose, xylose, and arabinose, which can be relatively easily processed into value-added bioproducts. The bioconversion platform also generates a quantity of lignin or lignin components; depending upon the pretreatment, lignin components may be found in the hydrolysate after enzymatic hydrolysis, or in the wash from the pretreatment stage.

Once hydrolyzed, six-carbon sugars can be fermented to ethanol using age-old yeasts and processes. Five-carbon sugars, however, are more difficult to ferment; new yeast strains are being developed that can process these sugars, but issues remain with process efficiency and the length of fermentation. Other types of fermentation, including bacterial fermentation under aerobic and anaerobic conditions, can produce a variety of other products from the sugar stream, including lactic acid.

Biodegradation

Biodegradation (transformation of a chemical by microorganisms) is the decay or breakdown of chemicals that occurs when microorganisms use an organic substance as a source of carbon and energy. For example, sewage flows to the wastewater treatment plant where many of the organic compounds are broken down; some compounds are simply biotransformed (changed), others are completely mineralized. These biodegradation processes are essential to recycle wastes so that the elements in them can be used again. Recalcitrant materials, which are hard to break down, may enter the environment as contaminants.

Another term, biotransformation, refers to the conversion of a substance through metabolization, thereby causing an alteration to the substance by biochemical processes in an organism. Metabolism is divided into the two general categories of catabolism, which is the breaking down of more complex molecules, and anabolism, which is the building up of life molecules from simpler chemicals. The substances subjected to biotransformation may be naturally occurring or anthropogenic (made by human activities) which may consist of xenobiotic molecules that are foreign to living systems.

Biodegradation is a microbial process that occurs when all of the nutrients and physical conditions involved are suitable for growth. Temperature is an important variable; keeping a substance frozen can prevent biodegradation. Most biodegradation occurs at temperatures between 10 and 35°C (50 and 95°F), and water is essential for the biodegradation process. Bacteria and fungi, including yeasts and molds, are the microorganisms responsible for biodegradation. The biodegradation of organic matter in the aquatic and terrestrial environments is a crucial environmental process. Some organic pollutants are biocidal; for example, effective fungicides must be antimicrobial in action. Therefore, in addition to killing harmful fungi, fungicides frequently harm beneficial saprophytic fungi (fungi that decompose dead organic matter) and bacteria. Herbicides are designed for plant control, and insecticides are used to control insects.

The biodegradation process can be divided into three stages: (i) biodeterioration, (ii) biofragmentation, and (iii) assimilation. The first stage (biodeterioration) is often described as a surface-level degradation that modifies the chemical, physical, and mechanical properties of the contaminant and occurs when the material is exposed to abiotic factors in the environment and allows for further degradation by weakening the structure of the contaminant. Some abiotic factors that influence these initial changes are compression (mechanical), light, temperature, and chemicals in the environment. While biodeterioration typically occurs as the first stage of biodegradation, it can in some cases occur in parallel (simultaneously) to biofragmentation which is the conversion of the spilled chemical to lower molecular weight fragments that are more amenable to removal from the environment (or ecosystem). Assimilation occurs when the fragment (or fragments) are assimilated into the environment (or ecosystem) without any deleterious effect to the system.

The resulting products from biofragmentation can be assimilated into microbial cells; this is the assimilation stage. Some of the products from fragmentation are easily transported within the cell by membrane carriers. However, other products of the biofragmentation stage still have to undergo biotransformation reactions to yield products that can then be transported inside the cell. Once inside the cell, the products enter catabolic pathways that either lead to the production of adenosine triphosphate (ATP) or elements of the structure of the cell.

The biodegradation process is, in general, an important process for the removal of chemical compounds (especially organic chemicals) from the environment. The versatility and activity of microbial enzymes as catalysts mean that biodegradation is much more significant than purely chemical reactions such as hydrolyses and redox reactions. Enzymatically catalyzed transformation also occurs in higher organisms, but this process is quantitatively less important than the contribution from microorganisms. Some of the most important microorganism-mediated chemical reactions in aquatic and soil environments are those involving nitrogen compounds and the cycle of such compounds throughout the Earth system. Among the biochemical transformations in the nitrogen cycle are (i) nitrogen fixation, whereby molecular nitrogen is fixed as organic nitrogen, (ii) nitrification, the process of oxidizing ammonia to nitrate, (iii) nitrate reduction in which nitrogen in nitrate ions is reduced to nitrogen in a lower oxidation state, and (iv) denitrification, the reduction of nitrate and nitrite to ammonia.

Physical-chemical and biological treatment processes are employed as for wastewater treatment. In addition, chemicals are introduced for precipitation of nutrients, followed by coagulation and filtration for removing solids remaining after biological treatment. In some cases, granular activated carbon or membrane filtration or a combination of membrane-assisted solvent extraction is used for additional purification of the groundwater streams and waste streams. This higher level of treatment is advisable because of the damage that any visual traces of chemical waste can do to the appearance of the waters. In addition, the treatment may combat the potential eutrophic effect that the nutrients phosphorus and nitrogen can have on a water system.

For the most part, anthropogenic compounds resist biodegradation much more strongly than do naturally occurring compounds. This is generally due to the absence of enzymes that can cause an initial attack on the compound. A number of physical and chemical characteristics of a compound are involved in its amenability to biodegradation. Such characteristics include hydrophobicity, solubility, volatility, and affinity for lipids. Some organic structural groups impart particular resistance to biodegradation. These structural groups include branched carbon chains, ether linkages, meta-substituted benzene rings, chlorine, amines, methoxy groups, sulfonates, and nitro groups.

Usually the products of biodegradation are molecular forms that tend to occur in nature and that are in greater thermodynamic equilibrium with their surroundings than the starting materials. Detoxification refers to the biological conversion of a toxic chemical to a less toxic chemical species.

The biodegradability of a compound is influenced by its physical characteristics, such as solubility in water and vapor pressure, and by its chemical properties, including molecular mass, molecular structure, and presence of various kinds of functional groups, some of which provide a "biochemical handle" for the initiation of biodegradation. With the appropriate organisms and under the right conditions, even substances such as phenol that are considered to be biocidal to most microorganisms can undergo biodegradation.

Biodegradation – In Situ

In situ techniques do not require excavation of the contaminated soils, so it may be less expensive, create less dust, and cause less release of contaminants than ex situ techniques. Also, it is possible to treat a large volume of soil at once. In situ techniques, however, may be slower than ex situ techniques, may be difficult to manage, and are most effective at sites with permeable soil (i.e., sandy or uncompacted soil).

The goal of aerobic in situ biodegradation is to supply oxygen and nutrients to the microorganisms in the soil. Aerobic in situ techniques can vary in the way they supply oxygen to the organisms that degrade the contaminants. Two such methods are (i) bioventing and (ii) injection of hydrogen peroxide. Oxygen can be provided by pumping air into the soil above the water table (bioventing) or by delivering the oxygen in liquid form as hydrogen peroxide. In situ biodegradation may not work well in clays or in highly layered subsurface environments because oxygen cannot be evenly distributed throughout the treatment area. In situ remediation often requires years to reach cleanup goals, depending mainly on how biodegradable specific contaminants are. Less time may be required with easily degraded contaminants.

Bioventing systems deliver air from the atmosphere into the soil above the water table through injection wells placed in the ground where the contamination exists. The number, location, and depth of the wells depend on many geological factors and engineering considerations. An air blower may be used to push or pull air into the soil through the injection wells. Air flows through the soil, and the oxygen in it is used by the microorganisms. Nutrients may be pumped into the soil through the injection wells. Nitrogen and phosphorous may be added to increase the growth rate of the microorganisms.

Injection of hydrogen peroxide is a process that delivers oxygen to stimulate the activity of naturally occurring microorganisms by circulating hydrogen peroxide through contaminated soils to speed up the biodegradation of organic contaminants. Since it involves putting a chemical (hydrogen peroxide) into the ground (which may eventually seep into the groundwater), this process is used only at sites where the groundwater is already contaminated. A system of pipes or a sprinkler system is typically used to deliver hydrogen peroxide to shallow contaminated soils. Injection wells are used for deeper contaminated soils.

The in situ biodegradation of groundwater speeds up the natural biodegradation processes that take place in the water-soaked underground region that lies below the water table. For sites at which both the soil and groundwater are contaminated, this single technology is effective at treating both.

Generally, an in situ groundwater biodegradation system consists of an extraction well to remove groundwater from the ground, an above-ground water treatment system where nutrients and an oxygen source may be added to the contaminated groundwater, and injection wells to return the “conditioned” groundwater to the subsurface where the microorganisms degrade the contaminants. A limitation of this technology is that differences in underground soil layers and differences in the density of each of the layers may cause reinjected conditioned groundwater to follow certain preferred flow paths and, consequently, the conditioned water may not reach some areas of contamination.

Another frequently used method of in situ groundwater treatment is *air sparging* (also known as in situ air stripping and in situ volatilization), which involves pumping air into the groundwater to help flush out contaminants and is often used in conjunction with a technology called soil vapor extraction.

The air sparging method is used for the treatment of saturated soils and groundwater contaminated with volatile organic compounds (VOCs). Typically, the process involves the use of multiple air injection points and multiple soil vapor extraction points that can be installed in contaminated soils to extract vapor phase contaminants above the water table. Contamination must be at least 3 ft deep beneath the ground surface in order for the system to be effective. A blower is attached to wells, usually through a manifold, below the water table, creating pressure. The pressurized air forms small bubbles that travel through the contamination in and above water column. The bubbles of air volatilize contaminants and carry them to the unsaturated soils above. Vacuum points are installed in the unsaturated soils above the saturated zone and facilitate the extraction of the vapors through a soil vapor extraction system. In order for the vacuum to avoid pulling the air from the surface, the ground has to be covered with a tarp or other method of sealing out surface air to prevent vapors from breaking through to the surface above. Surface air intrusion into the system reduces efficiency and can reduce the accuracy of system metrics.

While the air sparging system typically treats the off-gases (referred to as contaminated vapors and extracted air), the process can also be employed to treat arsenic-contaminated groundwater treated by air sparging and what the treatment does is to remove arsenic at a certain percentage using a solution of iron and arsenic.

One of the advantages of in situ biodegradation is that it can be effectively applied to treat wastes in place. The process usually entails introduction of nutrients, microorganism, and air to the soil/waste through a series of injection wells or infiltration trenches. The term bioventing has also been applied to this technology, although the term could just as easily be applied to composting or to soil heaping.

If the soil does not have sufficient moisture content, water may also have to be added. In situ biodegradation is often applied in conjunction with groundwater pump and treat systems and soil flushing activities.

There is also the concept of gene manipulation as a means degrading polynuclear aromatic hydrocarbon derivatives. The concept offers promise for many sites (such as town gas sites where wastes containing polynuclear aromatic hydrocarbon derivatives are evident). However, the degradation products from such interactions may require cleanup. But it is quite possible that the degradation products are easier to clean than the original polynuclear aromatic hydrocarbon derivatives. There is also the concept of using biodegradation on such wastes where the waste has been reduced to residual saturation by flushing technologies. A final flushing to remove the biodegraded material will be necessary.

Biodegradation Processes

Biodegradation (transformation of a chemical by microorganisms) is the decay or breakdown of chemicals that occurs when microorganisms use an organic substance as a source of carbon and energy. For example, sewage flows to the wastewater treatment plant where many of the organic compounds are broken down; some compounds are simply biotransformed (changed), others are completely mineralized. These biodegradation processes are essential to recycle wastes so that the elements in them can be used again. Recalcitrant materials, which are hard to break down, may enter the environment as contaminants.

Biodegradation is a microbial process that occurs when all of the nutrients and physical conditions involved are suitable for growth. Temperature is an important variable; keeping a substance frozen can prevent biodegradation. Most biodegradation occurs at temperatures between 10 and 35°C (50 and 95°F), and water is essential for the biodegradation process. Bacteria and fungi, including yeasts and molds, are the microorganisms responsible for biodegradation. The biodegradation of organic matter in the aquatic and terrestrial environments is a crucial environmental process. Some organic pollutants are biocidal; for example, effective fungicides must be antimicrobial in action. Therefore, in addition to killing harmful fungi, fungicides frequently harm beneficial saprophytic fungi (fungi that decompose dead organic matter) and bacteria. Herbicides are designed for plant control, and insecticides are used to control insects.

The biodegradation process can be divided into three stages: (i) biodeterioration, (ii) biofragmentation, and (iii) assimilation. The first stage (biodeterioration) is often described as a surface-level degradation that modifies the chemical, physical, and mechanical properties of the contaminant and occurs when the material is exposed to abiotic factors in the environment and allows for further degradation by weakening the structure of the contaminant. Some abiotic factors that influence these initial changes are compression (mechanical), light, temperature and chemicals in the environment. While biodeterioration typically occurs as the first stage of biodegradation, it can in some cases occur in parallel (simultaneously) to biofragmentation which is the conversion of the spilled chemical to lower molecular weight fragment that are more amenable to removal from the environment (or ecosystem). Assimilation occurs when the fragment (or fragments) are assimilated into the environment (or ecosystem) without any deleterious effect to the system.

On the other hand, the resulting products from biofragmentation can be assimilated into microbial cells this is the assimilation stage. Some of the products from fragmentation are easily transported within the cell by membrane carriers. However, other products of the biofragmentation stage still have to undergo biotransformation reactions

to yield products that can then be transported inside the cell. Once inside the cell, the products enter catabolic pathways that either lead to the production of adenosine triphosphate (ATP) or elements of the structure of the cell.

By way of explanation, the catabolic pathways are those metabolic pathways that break down molecules into smaller units that are either oxidized to release energy or used in other reactions. Catabolism breaks down larger molecules into smaller units and is, in fact, the molecular breaking-down aspect of metabolism, whereas anabolic pathways are the building-up aspect.

The biodegradation of the chemicals that occur in crude oil and crude oil products is essential to the elimination of the harmful effects of these spills. This oil is degraded by both marine bacteria and filamentous fungi. The physical form of crude oil makes a large difference in its potential for degradation. Degradation in water occurs at the water-oil interface. Therefore, thick layers of crude oil prevent contact with bacterial enzymes and oxygen. Apparently, bacteria synthesize an emulsifier that keeps the oil dispersed in the water as a fine colloid and is therefore accessible to the bacterial cells.

The biodegradation process is, in general, an important process for the removal of chemical compounds (especially organic chemicals) from the environment. The versatility and activity of microbial enzymes as catalysts mean that biodegradation is much more significant than purely chemical reactions such as hydrolyses and redox reactions. Enzymatically catalyzed transformation also occurs in higher organisms, but this process is quantitatively less important than the contribution from microorganisms. Some of the most important microorganism-mediated chemical reactions in aquatic and soil environments are those involving nitrogen compounds and the cycle of such compounds throughout the Earth system. Among the biochemical transformations in the nitrogen cycle are (i) nitrogen fixation, whereby molecular nitrogen is fixed as organic nitrogen, (ii) nitrification, the process of oxidizing ammonia to nitrate, (iii) nitrate reduction in which nitrogen in nitrate ions is reduced to nitrogen in a lower oxidation state, and (iv) denitrification, the reduction of nitrate and nitrite to ammonia.

Biodegradation of phosphorus compounds is important in the environment for two reasons. The first of these is that it provides a source of algal nutrient orthophosphate from the hydrolysis of polyphosphates. Secondly, biodegradation deactivates highly toxic organophosphate compounds, such as the organophosphate insecticides. The organophosphorus compounds of greatest environmental concern tend to be sulfur-containing phosphorothionate and phosphorodithioate ester insecticides. These are used because they exhibit higher ratios of insect: mammal toxicity than do their non-sulfur analogs. The biodegradation of these compounds is an important environmental chemical process. Fortunately, unlike the organic halogen insecticides that they largely displaced, the organophosphates readily undergo biodegradation and do not accumulate.

Sulfur compounds are common in water. Sulfate ions (SO_4^{2-}) are found in varying concentration in practically all natural waters. Organic sulfur compounds, both those of natural origin and pollutant species, are common in natural aquatic systems, and the degradation of these compounds is an important microbial process. Sometimes, the degradation products, such as the odorous and toxic hydrogen sulfide, cause serious problems with water quality.

One consequence of bacterial action on metal compounds is the occurrence of drainage of acidic aqueous solutions from mines (Hall, 2006). Acid mine drainage is a common and damaging problem in the waters flowing from coal mines, and draining from the spoil piles (mine tippage, gob piles) left over from coal processing and washing is highly acidic and has the ability to sterilize the surrounding land and water systems with the ensuing serious (often fatal) effects on the flora and fauna.

Acidic mine water results from the presence of sulfuric acid produced by the oxidation of pyrite (FeS_2). Microorganisms are involved in the overall process. The prevention and cure of acid mine water is a major challenge facing the environmental chemist. Selenium is also subject to bacterial oxidation and reduction. These transitions are important because selenium is a crucial element in nutrition, particularly of livestock. Microorganisms are involved with the selenium cycle, and microbial reduction of oxidized forms of selenium has been known for some time. A soil dwelling strain of *Bacillus megaterium* has been found to be capable of oxidizing elemental selenium to selenite (SeO_3).

Biodegradation – Slurry Phase

Slurry phase biodegradation (also known as bioreactor remediation) is a relatively more rapid process compared to the other treatment processes. The process is a controlled treatment process that involves the excavation of the contaminated soil, mixing it with water, and placing it in a bioreactor.

In the process, contaminated soil is combined with water and other additives in a large tank (the bioreactor) and mixed to keep the microorganisms, which are already present in the soil, in contact with the contaminants in the soil. Nutrients and oxygen are added, and conditions in the bioreactor are controlled to create the optimum environment for the microorganisms to degrade the contaminants. When the treatment is complete, the water is removed from the solids, which are sent for disposal or treated further if they still contain pollutants.

Slurry reactors or aqueous reactors are used for ex situ treatment of contaminated soil and water pumped up from a contaminated plume. Biodegradation in reactors involves the processing of contaminated solid material such as soil, sediment, sludge, or water through an engineered containment system.

A slurry bioreactor is a containment vessel and apparatus used to create a three- phase system, such as solid, liquid, and gas, mixing condition to increase the biodegradation rate of soil-bound pollutants and water-soluble pollutants as a water slurry of the contaminated soil and biomass capable of degrading target contaminants.

In general, the rate and extent of biodegradation are greater in a bioreactor system than in situ or in solid-phase systems because the contained environment is more manageable and hence more controllable and predictable. However, the contaminated soil may require pretreatment or, alternatively, the contaminant can be stripped from the soil via soil washing or physical extraction before being placed in a bioreactor.

See also: Biodegradation, Biodegradation In Situ, Biodegradation Processes, Biodegradation – Solid Phase.

Biodegradation – Solid Phase

Solid-phase biodegradation, often referred to as land farming, treats wastes using conventional soil management practices to enhance the microbial degradation of the wastes. Land farming is a relatively simple technique in which contaminated soil is excavated and spread over a prepared bed and periodically tilled until pollutants are degraded. The goal is to stimulate indigenous biodegradative microorganisms and facilitate their aerobic degradation of contaminants. In general, the practice is limited to the treatment of superficial 4 to 8 in. of soil. Since land farming has the potential to reduce monitoring and maintenance costs, as well as cleanup liabilities, it has received much attention as a disposal alternative. Nutrients and minerals are also added to promote the growth of the indigenous species.

Typically, the process requires excavation of contaminated soil or pumping of groundwater to facilitate microbial degradation. Ex situ biodegradation techniques involve the excavation or removal of contaminated soil from the ground. Depending on the state of the contaminant to be removed, ex situ biodegradation is classified as (i) a solid-phase system, which includes land treatment and soil piles or (ii) a slurry-phase system, which includes solid-liquid suspensions in bioreactors. A particular advantage of the ex-situ biodegradation process is that the process requires less time than the in situ process. Another advantage is the certainty of the control treatment due to the ability to uniformly screen, homogenize, and mix the soil. Ex-situ treatment technology is further divided into solid-phase biodegradation and slurry-phase biodegradation.

Solid-phase biodegradation is an ex-situ technology in which the contaminated soil is excavated and placed into piles. Bacterial growth is stimulated through a network of pipes that are distributed throughout the piles. By pulling air through the pipes, the necessary ventilation is provided for microbial respiration. Moisture is introduced by spraying the soil with water. Solid-phase systems require a large amount of space, and cleanups require more time to complete than with slurry-phase processes.

Biopiles are a hybrid of land farming and composting. Biopiles provide a favorable environment for indigenous aerobic and anaerobic microorganisms. Soil biopiles (also called biocells or bio-cells) are a biodegradation technique used for the remediation of excavated soil contaminated with crude oil and/or crude oil products. This technology involves the accumulation of contaminated soil into piles and the stimulation of microbial activity either aerobically or by the addition of nutrients, minerals or moisture. A typical height of biopiles is between 3 and 10 ft. Biopiles are

in a way similar to land farms due to the fact that this technology also uses oxygen as a way to stimulate bacterial growth. However, while tilling or plowing aerates land farms, biopiles are aerated by forcing air to move by injection through perforated piping placed throughout the pile. The soil is usually mixed with a bulking agent (such as straw) to improve aeration and therefore enhance the growth of the microbial population.

Nutrients and microorganisms are normally added to the wastes which are routinely tilled during the treatment process. This tilling improves aeration and the contact of the organisms with the wastes. While treatment may occur throughout the upper 3 to 5 ft of the soil, most occurs within the top foot, called the zone of incorporation.

Composting of chemical wastes is the biodegradation of solid or solidified materials in a medium other than soil. Bulking material, such as plant residue, paper, municipal refuse, or sawdust, may be added to retain water and enable air to penetrate to the waste material. Successful composting of chemical waste depends upon a number of factors, such as the selection of the appropriate microorganism or inoculum. Once a successful composting operation is underway, a good inoculum is maintained by recirculating spent compost to each new batch.

Other parameters that must be controlled include oxygen supply, moisture content (which should be maintained at a minimum of approximately 40% w/w), pH (usually around neutral), and temperature. The composting process generates heat, so, if the mass of the compost pile is sufficiently high, it can be self-heating under most conditions. Some wastes are deficient in nutrients, such as nitrogen, which must be supplied from commercial sources or from other wastes.

Soil heaping is piling wastes in heaps of several feet high on an asphalt or concrete pad. Nutrients, microorganisms, and air are provided through perforated piping placed throughout the pile. The pile is covered to contain volatile organic compounds, to stabilize the environment of the microorganisms, and to control soil erosion. The volatile organic compounds can be further controlled by applying a vacuum to the pile and treating the exhaust.

In this process, the wastes are normally mixed with a structurally firm bulking material such as chopped hay and wood chips. As with the other biodegradation technologies, nutrients, air, and microorganism must be added. The three major types of composting are open windrow, static windrow, and reactor systems. The differences among the three relate to how aeration is accomplished. In the open window system, the compost piles are open to the air, whereas in the static windrow system, the air is mechanically forced into the compost piles. When reactors are used, the compost is mechanically mixed to ensure aeration.

BioDeNOx Process

In addition, the BioDeNOx process is a biological process removes nitrogen oxides from flue gases. An iron chelate selectively absorbs the nitrogen oxides which are reduced to nitrogen with ethanol in the presence of microorganisms. Then, a wet gas scrubber is used to contact the circulation liquid with flue gas feed and absorb the nitrogen oxides (NOx).

In the sump underneath the scrubber, the absorbed nitrogen oxides are biologically reduced to nitrogen and ethanol is also consumed and, thus, the iron chelate solution is regenerated. The presence of oxygen and acid compounds in the flue gas, such as hydrogen chloride and hydrogen fluoride, oxidizes a part of iron chelate to the ferric (Fe^{3+}) state. Therefore, a purge and makeup of iron chelate is necessary to eliminate this oxidized ferric material. To minimize iron chelate consumption, a nano-filtration can be installed and bleed from the unit is passed through the filter and the chelate is recovered.

BioDesulfurization

The biocatalyst desulfurization of a fuel is one of a number of possible modes of applying biologically-based processing to the needs of the renewable fuel industry. In addition, mycobacterium goodii has been found to desulfurize benzothiophene to produce α -hydroxystyrene.

Biodesulfurization is a technology to remove sulfur from the feedstock. However, several factors may limit the application of this technology. Many ancillary processes novel to crude oil refining would be needed, including a biocatalyst fermenter to regenerate the bacteria. The process is also sensitive to environmental conditions such as sterilization, temperature, and residence time of the biocatalyst. Finally, the process requires the existing hydrotreater to continue in operation to provide a lower sulfur feedstock to the unit and is more costly than conventional hydrotreating. Nevertheless, the limiting factors should not stop the investigations of the concept and work should be continued with success in mind.

Biodiesel

The term biodiesel refers to any diesel fuel substitute derived from renewable biomass. More specifically, biodiesel refers to a family of products made from vegetable oils or animal fats and alcohol, such as methanol or ethanol, called alkyl esters of fatty acids. For these to be considered as viable transportation fuels, they must meet stringent quality standards. In most contexts, unless otherwise stated, biodiesel refers to the alkyl esters produced by transesterification of vegetable oils or animal fats.

*Ethanol (ethyl alcohol, $\text{C}_2\text{H}_5\text{OH}$) could also be used.

Biodiesel is an alternative to crude oil-based fuels. Biodiesel is made from a variety of natural oils, especially rapeseed oil (a close cousin of canola oil) and soybean oil. Rapeseed oil tends to dominate the growing biodiesel industry in Europe, whereas in the United States, biodiesel is made from soybean oil because more soybean oil is produced here than all other sources of fats and oil combined. Palm and Jatropha oil are favored in Asian countries, but there are many other feedstock candidates, including recycled cooking oils, animal fats, and other oilseed crops.

Biodiesel is a renewable fuel that can be manufactured from algae, vegetable oils, animal fats, or recycled restaurant greases; it can be produced locally in most countries. It is safe, biodegradable, and reduces air pollutants, such as particulates, carbon monoxide, and hydrocarbon derivatives. Blends of 20% biodiesel with 80% crude oil diesel (B20) can generally be used in unmodified diesel engines. Biodiesel can also be used in its pure form (B100), but may require certain engine modifications to avoid maintenance and performance problems.

Biodiesel is made by chemically reacting vegetable oil or animal fat (or combinations of oils and fats) with alcohol (usually nearly pure methanol or ethanol) and a catalyst (sodium hydroxide). The chemical reaction converts constituents of the vegetable oil into an ester (biodiesel fuel) and glycerol. Since the biodiesel is less dense than the glycerol, it floats on top of the glycerol and may be pumped off, or the glycerol can be drained off the bottom. The fuel can then be filtered and used in heating or lighting applications. It is possible to use the product in diesel engines without further processing, but caution is advised because of the potential for engine damage and it is recommended that impurities (unreacted alcohol and sodium hydroxide) are removed by a washing.

Biodiesel is currently produced entirely from vegetable oil, waste cooking oil, animal fats, and algae. It is named biodiesel because it is derived from biological product and has similar physical properties as petro diesel. The biodiesel feedstock (oil and fats) primarily consists of triglycerides and have some amount of free fatty acids depending on their origin. The high viscosity and poor combustion properties of vegetable oils (compared to petro diesel) do not allow them to use directly as diesel substitute in engines. The direct use of vegetable oils can give rise to significant carbon deposit, lubricating oil contamination, excessive engine wear, and thus reduced engine durability. The processes such as transesterification, pyrolysis, catalytic cracking, and non-catalytic cracking have evolved to transform the vegetable oils or fats into biodiesel (fatty acid methyl ester) or biofuel.

Biodiesel is composed of long-chain fatty acids with an alcohol attached, often derived from vegetable oils. It is produced through the reaction of a vegetable oil with methyl alcohol or ethyl alcohol in the presence of a catalyst. Animal fats are another potential source. Commonly used catalysts are potassium hydroxide (KOH) or sodium hydroxide (NaOH). The chemical process is called transesterification which produces biodiesel and glycerin. Chemically, biodiesel is called a methyl ester if the alcohol used is methanol. If ethanol is used, it is called an ethyl

ester. They are similar, and currently, methyl ester is cheaper due to the lower cost for methanol. Biodiesel can be used in the pure form, or blended in any amount with diesel fuel for use in compression ignition engines.

Biodiesel is typically produced through the reaction of a vegetable oil or animal fat with methanol or ethanol in the presence of a catalyst to yield glycerin and mono-alkyl esters. If methanol is used as the alcohol for transesterification, the reaction is referred to as methanolysis and methyl esters are produced, whereas ethyl esters are produced when ethanol is used for transesterification (ethanolysis). However, it is important to point out that glycerin is considered a valuable co-product that can be used in pharmaceuticals, cosmetics, and many other applications, depending on its grade and purity. The process can be represented simply as:

Vegetable oil $\rightarrow$ transesterification/methanol $\rightarrow$ glycerol/methanol + crude biodiesel

Vegetable oil $\rightarrow$ transesterification/ethanol $\rightarrow$ glycerol/ethanol + crude biodiesel

Glycerol/methanol $\rightarrow$ refining $\rightarrow$ glycerol + methanol

Glycerol/ethanol $\rightarrow$ refining $\rightarrow$ glycerol + ethanol

Crude biodiesel $\rightarrow$ biodiesel

The process involves treatment of raw vegetable oils at low temperatures of 30 to 40°C (86 to 104°F) with methanol or ethanol in the presence of a catalyst such as sodium or potassium hydroxide (transesterification). Glycerol is produced and immediately settles out because of its low solubility in the ester product, carrying most of the dissolved catalyst with it. The upper layer containing the desired product is washed thoroughly to remove any residual catalyst and other emulsion-forming contaminants, yielding a clear, dark yellow material that can be directly used as a diesel substitute after dehydration. Phase separation can only be attained in ethanolysis under complete absence of water, whereas this process is often easier when methanol is used for transesterification.

Biodiesel may be made from virtually any oil-containing or oil-producing vegetation, including the seeds from rape, soybean, sunflower, peanut, cotton, castor and palm, or even animal fats. Other tropical oilseeds are also amenable to biodiesel production, such as *Ricinus communis* (mamona), *Jatropha curcas* (Jatropha), and *Cyperus esculentus* (tigernut). It may also be made from waste vegetable oils and fats from fish and chip or fried chicken establishments. The manufacturing process is totally benign, having no detrimental effect on the environment.

Biodiesel has a strong ecological appeal and many reasons have been claimed to support its utilization as a diesel substitute. In general, these include: (i) biodiesel is biodegradable and harmless, (ii) biodiesel can be produced from renewable materials such as vegetable oils and ethanol derived from biomass, (iii) methyl esters usually contain little sulfur (approximately 0.001% w/w) while this undesired component is literally absent in biodiesel produced by ethanolysis, (iv) biodiesel is a diesel substitute, biodiesel decreases soot emission considerably (up to 50%), (v) biodiesel emits approximately the same amount of carbon dioxide that has been absorbed during cultivation of the oilseed, (vi) biodiesel does not contain any of the carcinogenic polyaromatic components found in diesel oil, (vii) biodiesel has been recognized as a suitable outlet for the vegetable oil industry, serving as an important tool for market regulation, (viii) biodiesel can be used in blends or as a neat fuel, (ix) biodiesel is not considered as a hazardous good because it has a flash point above 110°C (230°F), (x) biodiesel has a superior lubrication capability and increases engine life, and (xi) biodiesel can be produced with a rather straight forward technology, particularly in the case of methyl esters (methanolysis).

The use of biodiesel in a conventional diesel engine also results in substantial reduction of unburned hydrocarbon derivatives, carbon monoxide, and particulate matter. Emissions of nitrogen oxides are either slightly reduced or slightly increased depending on the duty cycle and testing methods. The higher oxygen content of biodiesel enables a more complete combustion of the solid carbon fraction to carbon dioxide, while soluble hydrocarbon derivatives are unaffected or even increased.

Producers and users of biodiesel use the "B" factor system to state the amount of biodiesel in a fuel mix, similar to the "E" system used for fuel containing ethanol. For example, fuel containing 20% biodiesel is labeled B20, whereas pure biodiesel is referred to as B100.

Biodiesel Feedstocks

A major focus has been and continues to be on biofuels produced from crops, such as corn, sugar cane, and soybeans, for use as renewable energy sources. Though it may seem beneficial to use renewable plant materials for biofuel, the use of crop residues and other biomass for biofuels raises many concerns related to major environmental problems, including food shortages and serious destruction of vital soil resources. Examples of feedstock for the production of biodiesel are (i) waste vegetable oil, (ii) animal fat including tallow, lard, yellow grease, chicken fat, and the by-products of the production of fatty acids from fish oil, and soybeans which are also used as a source of biodiesel (Table B-4).

Table B-4 Composition of various oils and fats used for biodiesel production.

Oil or Fat	14:0*	16:0	18:0	18:1	18:2	18:3
Corn oil	1-2	8-12	2-5	19-49	34-52	Trace
Cottonseed oil	0-2	20-25	1-2	23-35	40-50	Trace
Linseed oil		4-7	2-4	25-40	35-40	25-60
Olive oil		9-10	2-3	73-84	10-12	Trace
Peanut oil		8-9	2-3	50-60	20-30	
Safflower oil – Hi linoleic acid		5.9	1.5	8.8	83.8	
Safflower oil – Hi oleic acid		4.8	1.4	74.1	19.7	
Rapeseed oil – Hi oleic acid		4.3	1.3	59.9	21.1	13.2
Rapeseed oil – Hi erucic acid		3.0	0.8	13.1	14.1	9.7
Soybean oil		6-10	2-5	20-30	50-60	5-11
Tallow	3-6	24-32	20-25	37-43	2-3	
Yellow grease	2	23	13	44.3	7	0.7

*Indicates the number of carbon atoms in the alkyl chain and the position of the double bond.

However, for a given production line, the comparison of the feedstocks includes several issues which are (i) chemical composition of the biomass, (ii) cultivation practices, (iii) availability of land and land use practices, (iv) use of resources, (v) energy balance, (vi) emission of greenhouse gases, acidifying gases, and ozone depletion gases, (vii) absorption of minerals to water and soil, (viii) injection of pesticides, (ix) soil erosion, (x) contribution to biodiversity and landscape value losses, (xi) farm-gate price of the biomass, (xii) logistic costs such as transport and storage of the feedstock), (xiii) direct economic value of the feedstocks taking into account the co-products, (xiv) creation or maintenance of employment, and (xv) water requirements and water availability. In addition, different types of feedstocks have different types of fatty acids. The fatty acids are different in relation to the chain length, degree of unsaturation, or presence of other chemical functions, such as fatty acids.

Tropical countries have the highest potential to produce bio-fuel crops: higher energy yields, better greenhouse gas balance if properly produced, lower costs, and in some countries, large reserves of uncultivated cropland. Sugar cane and palm are the highest yielding tropical biofuel crops and consequently provide the greatest carbon offsets. Industrialized countries with biofuels targets (such as the United States and the EU countries) are unlikely to have the agricultural land base needed to meet their growing demand for current production of bio-fuels, which are largely produced from food and feed crops (e.g., maize, palm, rapeseed, soybean).

Of importance are the combustion and flow properties of biodiesel which are determined primarily by the fatty acid content of the vegetable oil which affect the fuel properties of the biodiesel. Biodiesel has lower volumetric heating values (approximately 12%) than crude oil-derived diesel fuel, but biodiesel has a high cetane number (between 46 and 70) and high flash point.

In comparison to crude oil-derived diesel, the higher cetane number of biodiesel results in (i) shorter ignition delay, (ii) longer combustion duration, (iii) low particulate emissions, and (iv) minimum carbon deposits on injector nozzles.

See also: Biochemical Platform, Biodiesel, Biofuels.

Waste cooking oil is a valuable asset for conversion to liquid fuels, and the quantity of biodiesel which could be produced from waste cooking oil can be quantified in a manner similar to that of biodiesel produced direct from agriculture. The only difference is that rather than calculating crop yields, it is necessary to quantify the amount of waste oil available.

Biodiesel is a light to dark yellow liquid that is immiscible with water and has a high boiling point, low vapor pressure, a flash point of approximately 150°C (300°F), and a density on the order of 0.88 g/cm³. Biodiesel has a viscosity similar to petrodiesel (the current term to differentiate the different forms of diesel) and can be used as an additive in formulations of diesel to increase the lubricity of pure ultra-low sulfur diesel (ULSD) fuel.

Almost any variety of oil or grease (from new food-grade vegetable oil to used cooking oil or trap grease to wastewater treatment-plant grease) can be converted into biodiesel. However, the amounts of reactants (oil, methanol, and sodium hydroxide) vary to some degree, depending on what oil is used. The amount of methanol and sodium hydroxide must be sufficient to react with the vegetable oil, but excessive amounts of these reactants should not be used. Just as an engine requires excess air to be sure that all the fuel burns, it takes excess methanol to be sure all of the oil reacts.

The chemistry of biodiesel production is known as transesterification insofar as the process involves reaction of glycoside-containing plant oil with a short chain alcohol such as methanol or ethanol. The feedstocks are typically animal, and plant fats and oils are typically made of triglycerides which are esters of free fatty acids with the trihydric alcohol, glycerol. In the transesterification reaction, the alcohol is deprotonated with a base to make it a stronger nucleophile. Commonly, ethanol or methanol is used. Usually, the reaction proceeds at a low rate; heat, as well as an acid or base, is used to help the reaction proceed more quickly.

Almost all biodiesel from waste oil is produced using the base-catalyzed technique as it is the most economical process, requiring only low temperatures and pressures and producing over 98% conversion yield (provided the starting oil is low in moisture and free fatty acids). The major steps required to synthesize biodiesel are purification, neutralization, and transesterification.

Purification: the waste vegetable oil is filtered to remove dirt, charred food, and other non-oil material often found. Water is removed because its presence causes the triglycerides to hydrolyze to give salts of the fatty acids instead of undergoing transesterification to give biodiesel. The crude oil may be stirred with a drying agent such as magnesium sulfate to remove the water in the form of water of crystallization. The drying agent can be separated by decanting or by filtration, but the viscosity of the oil may not allow the drying agent to mix thoroughly.

Neutralization of free fatty acids: A sample of the cleaned oil is titrated against a standard solution of base in order to determine the concentration of free fatty acids (RCOOH) present in the waste vegetable oil sample. The quantity of base required to neutralize the acid is then calculated.

Transesterification: While adding the base, a slight excess is factored in to provide the catalyst for the transesterification. The calculated quantity of base (usually sodium hydroxide) is added slowly to the alcohol, and it is stirred until it dissolves. Sufficient alcohol is added to make up three full equivalents of the triglyceride, and an excess is added to drive the reaction to completion. The solution of sodium hydroxide in the alcohol is then added to a warm solution of the waste oil, and the mixture is heated (typically 50°C, 122°F) for several hours (4 to 8 typically) to allow the transesterification to proceed. A condenser may be used to prevent the evaporative losses of the alcohol. Care must be taken not to create a closed system which can explode.

Workup: Once the reaction is complete, the glycerol should sink. When ethanol is used, it is reported that an emulsion often forms. This emulsion can be broken by standing, centrifugation, or the addition of a low boiling (easily removed) non-polar solvent, decanting, and distilling. The top layer, a mixture of biodiesel and alcohol, is decanted. The excess alcohol can be distilled off, or it can be extracted with water. If the latter is used, the biodiesel should be dried by distillation or with a drying agent.

Biodiesel – Production and Properties

Biodiesel is a diesel-equivalent fuel derived from biological sources (such as vegetable oil) which can be used in unmodified diesel-engine vehicles. It is thus distinguished from the straight vegetable oil or waste vegetable oil used as fuels in some diesel vehicles.

Biodiesel fuel is a fuel made from the oil of certain oilseed crops such as soybean, canola, palm kernel, coconut, sunflower, safflower, corn, and a hundreds of other oil-producing crops. The oil is extracted by the use of a press and then mixed in specific proportions with other agents, which causes a chemical reaction (Figure B-1). The results of this reaction are two products, biodiesel and soap. After a final filtration, the biodiesel is ready for use. After curing, the glycerin soap which is produced as a by-product can be used as is, or can have scented oils added before use.

Figure B-1 Biodiesel Production Path.

Biodiesel is made through a chemical process (transesterification) whereby the glycerin is separated from the fat or vegetable oil. The process leaves behind two products: (i) methyl esters and (ii) glycerin (a valuable by-product usually sold to be used in soaps and other products).

The primary products of transesterification are methyl esters (biodiesel) and glycerol. 100 lbs of soybean oil are reacted with 10 lbs of methanol and 1 lbs of catalyst yielding 100 lbs of biodiesel and 10 lbs of glycerol. Glycerol is decanted and removed first as it is heavier and sinks. Methanol is recycled in the process by washing both the glycerol and biodiesel with water to remove unreacted methanol and return it to the process. Glycerol, a valuable by-product, is approximately 88% pure and can be further processed to pharmaceutical grade glycerol.

Biodiesel is a liquid which varies in color between golden and dark brown depending on the feedstock from which it is produced. In general, biodiesel compares well to crude oil-based diesel (Table B-5). Pure biodiesel fuel (100% esters of fatty acids) is called B100. When blended with diesel fuel, the designation indicates the amount of B100 in the blend, e.g., B20 is 20% B100 and 80% diesel, and B5 used in Europe is contains 5% B100 in diesel.

Table B-5 Comparison of properties of biodiesel from various sources.

Property	Source: waste cooking oil	Source: animal tallow	Commercial diesel fuel
Density (kg/l at 15°C)	0.890 -0.897	0.856 - 0.877	0.075-0.840
Flash point (°C)	196	30 to 35	67 to 85
Pour point (°C)	11	-6 to 0	-19 to -13
Cetane number	54	58.8 - 61	40-46
Ash content (% w/w)	0.004	0.022 – 0.025	0.008-0.010
Sulfur content (% w/w)	0.06	0.18	0.35-0.55
Carbon residue (% w/w)	0.33	-	0.35-0.40
Water content (% w/w)	0.04	-	0.02-0.05

The properties of biodiesel compare very favorably with the properties of crude oil -derived diesel. For example: (i) biodiesel is a safe, non-toxic, biodegradable, and renewable fuel that produces lower regulated vehicle emissions, (ii) biodiesel is oxygenated and has a higher flashpoint making it safer to handle and store. Biodiesel also has a higher cetane number providing a smoother running engine and extending engine life, and (iii) biodiesel can also be used in locomotives, as heating oil, in generators, and as a bio-remediator in oil spills.

Biodiesel (fatty acid methyl esters; FAME) is a notable alternative to the widely used crude oil-derived diesel fuel since it can be generated by domestic natural sources such as soybeans, rapeseeds, coconuts, and even recycled cooking oil, and thus reduces dependence on diminishing crude oil fuel from foreign sources. In addition, because biodiesel is largely made from vegetable oils, it reduces lifecycle greenhouse gas emissions by as much as 78%.

Vegetable oils and animal fats belong to an extensive family of chemicals called lipids. Lipids are bio-products from the metabolism of living creatures. As a result, they can be found widely distributed in nature. Their bio-functions are diverse, but they are most known for their energy storage capacity. Most lipids can easily dissolve in common organic solvents, meaning that they are hydrophobic. If a lipid is a solid at 25°C (77°F), it is classified as a fat; otherwise, it is oil. Typically, fats are produced by animals and oils by plants, but both are mainly made of triglyceride molecules, which are tri-esters of glycerol (a triol) and free fatty acids (long alkyl chain carboxylic acids). Other glyceride species, such as di-glycerides and mono-glycerides, are obtained from triglycerides by the substitution of one and two fatty acid moieties, respectively, with hydroxyl groups.

Biodiesel production is a very modern and technological area for researchers due to the relevance that it is winning every day because of the increase in the crude oil price and the environmental advantages.

Biodiesel is biodegradable and non-toxic, and typically produces approximately 60% v/v less net carbon dioxide emissions than crude oil-based diesel, as it is itself produced from atmospheric carbon dioxide via photosynthesis in plants.

It is practically immiscible with water, and has a high boiling point and low vapor pressure. Typical methyl ester biodiesel has a flash point of approximately 150°C (300°F), making it rather non-flammable. Biodiesel has a density of approximately 0.88 g/cm³, less than that of water. Biodiesel uncontaminated with starting material can be regarded as non-toxic, but it is recommended that no one drink any!

Biodiesel has a viscosity similar to diesel produced from crude oil (petrodiesel). It can be used as an additive in formulations of diesel to increase the lubricity of pure ULSD fuel, which is advantageous because it has virtually no sulfur content.

Much of the world uses a system known as the “B” factor to state the amount of biodiesel in any fuel mix. For example, fuel containing 20% biodiesel is labeled B20. Pure biodiesel is referred to as B100. Blends of 20% biodiesel with 80% crude oil diesel (B20) can generally be used in unmodified diesel engines. Biodiesel can also be used in its pure form (B100), but may require certain engine modifications to avoid maintenance and performance problems. Biodiesel has approximately 5 to 8% less energy density, but better lubricity and more complete combustion can make the energy output of a diesel engine only 2% less per volume when compared to petrodiesel.

The higher lubricity index of biodiesel compared to petrodiesel is an advantage and can contribute to longer fuel injector life. However, biodiesel is a better solvent than crude oil-derived diesel, and has been known to break down deposits of residue in the fuel lines of vehicles that have previously been run on petrodiesel. As a result, fuel filters and injectors may become clogged with particulates if a quick transition to pure biodiesel is made, as biodiesel cleans the engine in the process.

The temperature at which pure (B100) biodiesel starts to gel varies significantly and depends upon the mix of esters and therefore the feedstock oil used to produce the biodiesel. For example, biodiesel produced from varieties of canola seed starts to gel at approximately -10 °C. Biodiesel produced from tallow tends to gel at around 16°C (61°F). Winter operation is possible with biodiesel blended with other fuel oils including #2 low-sulfur diesel and #1 diesel/kerosene, but the exact blend depends on the operating environment.

Biodiesel may contain small but problematic quantities of water. Although it is hydrophobic (non-miscible with water molecules), there are indications that biodiesel is said to be, at the same time, hygroscopic to the point of attracting water molecules from atmospheric moisture. In addition, there may be water that is residual to processing or resulting from storage tank condensation. The presence of water is a problem because (i) water reduces the heat of combustion of the bulk fuel which means more smoke, harder starting, and less power, (ii) water causes corrosion of vital fuel system components: fuel pumps, injector pumps, and fuel lines, (iii) water freezes to form ice crystals at

0°C (32 °F), and the crystals provide sites for nucleation and accelerate the gelling of the residual fuel, and (iv) water accelerates the growth of microbe colonies, which can plug up a fuel system and, in fact, biodiesel users who have heated fuel tanks therefore face a year-round microbe problem.

The extra lubrication provided by biodiesel fuel helps improve the longevity of the engine, as well as boosting engine performance, also helping eliminate engine knocks and noise. In addition, biodiesel fuel can be stored in any type of tank and has a much higher flash point (approximately 300°C, 570°F) compared to petrodiesel (approximately 150°C, 300°F).

Biodiesel – Technical Standards

The common international standard for biodiesel is EN 14214, while ASTM D6751 is the most common standard referenced in the United States and Canada (Table B-6). In Germany, the requirements for biodiesel are fixed in the DIN EN 14214 standard, and in the UK, the requirements for biodiesel is fixed in the BS EN 14214 standard, although these last two standards are essentially the same as EN 14214 and are just prefixed with the respective national standards institution codes.

Table B-6 Specifications for diesel and biodiesel (ASTM).

Property	Diesel	Biodiesel
Standard	ASTM D975	ASTM D6751
Composition	HC* (C10–C21)	FAME** (C12–C22)
Specific gravity (g/mL)	0.85	0.88
Flash point (°C)	60–80	100 - 170
Cloud point (°C)	-15 to 5	-3 to 12
Pour point (°C)	-35 to -15	-15 to 16
Water, % v/v	0.05	0.05
Carbon, wt%	87	77
Hydrogen, wt%	13	12
Oxygen, wt%	0	11
Sulfur, wt%	0.05	0.05
Cetane number	40–55	48 - 60

*HC: hydrocarbon derivatives

**FAME: fatty acid methyl esters

There are standards for three different varieties of biodiesel, which are made of different oils: (i) rapeseed methyl ester, DIN E51606, (ii) vegetable methyl ester, purely vegetable products, DIN E51606, and (iii) fat methyl ester, vegetable and animal products, according to DIN V51606. The standards ensure that the following important factors in the fuel production process are satisfied; there needs to be (i) complete reaction, (ii) removal of glycerin, (iii) removal of catalyst, (iv) removal of alcohol, (v) absence of free fatty acids, and (vi) low sulfur content.

Basic industrial tests to determine whether the products conform to the standards typically include gas chromatography, a test that verifies only the more important of the variables above. Fuel meeting the quality standards is very non-toxic, with a toxicity rating (LD50) of greater than 50 mL/kg.

Biodiesel has promising lubricating properties and cetane ratings compared to low sulfur diesel fuels. Fuels with higher lubricity may increase the usable life of high-pressure fuel injection equipment that relies on the fuel for its

lubrication. Depending on the engine, this might include high pressure injection pumps, pump injectors (also called *unit injectors*), and fuel injectors.

Generally, the heat content (calorific value) of biodiesel is lower than that of the regular crude oil-derived diesel, and variations in biodiesel energy density are more dependent on the feedstock used than the production process. Biodiesel can provide better lubricity and more complete combustion, thus increasing the engine energy output and partially compensating for the higher energy density of petrodiesel. The color of biodiesel ranges from golden to dark brown, depending on the production method. It is slightly miscible with water, has a high boiling point, and, consequently, a low vapor pressure. The flash point of biodiesel exceeds 130°C (266°F), which is significantly higher than that of crude oil-derived diesel which may be as low as 52°C (126°F). Biodiesel has a density of on the order of 0.88 g/cm³, higher than petrodiesel (which is approximately 0.85 g/cm³). Typically, biodiesel does not contain sulfur, and it is often used as an additive to ULSD fuel to aid with lubrication, as the sulfur compounds in petrodiesel provide much of the lubricity.

ASTM International (ASTM), formally known as the American Society for testing materials, is an international organization which develops and publishes information on the technical standards of various products, materials, systems, and services. It is one of the largest and most highly regarded standards development organizations in the world. The available literature on the performance of biofuels when compared with traditional fossil fuels normally uses ASTM and ISO (International Standards Organization) specifications and parameters. The specifications provide details on requirements for fuel characteristics as well as the relevant standard test methods to use for each.

Because of the focus on alternate fuel standards (particularly the standards for biodiesel) over the past two decades, the development of biodiesel standards started in the 1990s in order to support the increasing use of alkyl esters-based biodiesel and its blends as automotive fuels. The first ASTM standard (ASTM D6751) was adopted in 2002 while in Europe; EN 14214 biodiesel standard (based on former DIN 51606) was finalized in October 2003. The US and EU standards have international significance; they are usually the starting point for biodiesel specifications developed in other countries. However, in the United States, the standard (ASTM D6751) establishes specifications for a *biodiesel blend stock* for middle distillate fuels and, while the specification was written for B100, it is not intended for neat biodiesel used as automotive fuel. Rather, it is for the biodiesel component that is to be blended to produce biodiesel/diesel fuel blends. Since 2012, the ASTM D6751 standard has defined two grades of biodiesel (i) grade 2-B, which is identical to biodiesel defined by earlier versions of the standard, and (ii) grade 1-B, which has more strict controls on monoglycerides and cold soak filterability. In addition, the ASTM Standard Specification for Diesel Oil (ASTM D975) was modified in 2008 to allow up to 5% biodiesel to be blended into the fuel while a standard for biodiesel blends (ASTM D7467) is a specification for biodiesel blends from B6 to B20.

Most countries of the world use a system known as the “B” factor to state the amount of biodiesel in any fuel mix, in contrast to the “BA” or “E” system used for bioalcohol. Pure biodiesel is referred to as B100, while fuel containing 20% biodiesel is labeled “B20.” The common international standard for biodiesel is EN 14214, while ASTM 6751 is most referenced in the U.S. In Germany, the requirements for biodiesel are fixed in the DIN EN 14214 standard.

One of the most important fuel properties of biodiesel and conventional diesel fuel derived from crude oil is viscosity, which is also an important property of lubricants. Ranges of acceptable kinematic viscosity are specified in various biodiesel and crude oil standards. Reducing viscosity is one of the main reasons why vegetable oils or fats are transesterified to biodiesel because the high viscosity of neat vegetable oils or fats ultimately leads to operational problems such as engine deposits.

The viscosity of biodiesel is slightly greater than that of petrodiesel but approximately an order of magnitude less than that of the parent starting material (vegetable oil or fat). Biodiesel and its blends with petrodiesel display temperature-dependent viscosity similar to that of neat petrodiesel. Influencing factors are chain length, position, number, and nature of double bonds as well as the nature of the oxygenated moieties.

Generally, biodiesel has a higher cloud point (temperature at which a fuel becomes hazy or cloudy and starts to gel) than petrodiesel. This makes its use impractical in cooler climates and limits its potential market. Other important chemical and physical properties described in ASTM standards for biodiesel are acid number (TAN – total acid number, indicates the presence of free fatty acids and carboxylic acids present), corrosion (describes the potential for copper corrosion, measured using ASTM method D130), low temperature performance [describes pour points (PP), and cloud points (CP) using ASTM D5949 and ASTM D5773 methods], and oxidation stability (normally evaluated using Differential Scanning Calorimetry and Oxidation Stability Index). In addition, according to the EMA (Engine

Manufacturers Association), a blend of crude oil diesel fuel meeting ASTM D975 and 100% (neat) biodiesel fuel meeting either ASTM 6751 or EN 14214, where the biodiesel content of the blended fuel is no more than 20% biodiesel by volume (B20), shall meet the requirements identified in at the point of delivery of the fuel to the end user.

In terms of the effects of biodiesel on fuel filters, use of biodiesel blends which do not meet up to the designated specifications, have shown to drastically reduce filter life. Blends greater than B20 may have enough of a solvent to break down the varnish deposits on the walls of existing fuel storage tanks or fuel systems. The breakdown of these varnish deposits will contaminate the fuel with particulate, which can cause fuel filters to plug rapidly.

Another disadvantage of biodiesel is that it tends to reduce fuel economy. Energy efficiency is the percentage of the thermal energy of the fuel that is delivered as engine output, and biodiesel has shown no significant effect on the energy efficiency of any test engine. Volumetric efficiency, a measure that is more familiar to most vehicle users, is usually expressed as miles traveled per gallon of fuel (or kilometers per liter of fuel). The energy content per gallon of biodiesel is approximately 11% lower than that of crude oil diesel. Vehicles running on B20 are therefore expected to achieve 2.2% (20 % x 11 %) fewer miles per gallon of fuel.

Areas of concern and interest are for the biofuels industry to have in place a good quality control protocol for the measurement of bioalcohols, to avoid metal corrosion from water and acid corrosion (due to weak and strong acids and inorganic chlorides in solution). Also of importance are the limits set on phosphorous content (less than 5.0 mg/L in ethanol) to prevent engine catalyst deterioration, and copper content (less than 0.1 mg/kg), along with a sulfur content less than 10 mg/kg.

Up to a 10% blend level, the performance of bioethanol-blended gasoline is similar to ordinary gasoline. At higher levels, however, some engines may begin to exhibit problems, for example, stumbling under slight acceleration. The fuel also has more aggressive properties at higher concentrations of bioethanol which increases the possibility of deterioration of some components. Gasoline must be volatile enough to move from the carburetor or injectors into the cylinders and to vaporize prior to combustion. However, gasoline cannot have such a volatility that allows it to vaporize and boil in the injectors, carburetor, fuel lines, or fuel pump, which could prevent it from being metered correctly. Also, if the gasoline is too volatile, more evaporates into the air adding to environmental problems. There are a number of volatility specifications to ensure suppliers get this balancing act right. Adding bioethanol to gasoline as low-level blends increases the volatility of the blended fuel.

The Engine Fuel Specifications Regulations specify volatility measures for bioethanol-blended petrol. The limits for blends are similar to those for gasoline so as to ensure no changes in vehicles are required. Bioethanol introduces more oxygen into the fuel. In vehicles with simple fuel metering systems such as carburetors, this causes the mixture to become a little leaner. Leaning is good for fuel economy and is generally good for lowering some types of exhaust emissions. However, it may cause some engines to stumble if they are already tuned reasonably lean. If a vehicle stumbles on bioethanol-blended gasoline, re-tuning should solve the problem. A vehicle tuned correctly for use on ordinary gasoline would normally not exhibit problems when using bioethanol blends.

Biodiesel – Transesterification

Transesterification (alcoholysis) is the conversion of triacylglycerol lipids by alcohols to alkyl esters without first isolating the free fatty acids (May, 2004). The purpose of transesterification of vegetable oils to their methyl esters (biodiesel) process is to lower the viscosity of the oil. The transesterification reaction is affected by alcohol type, molar ratio of glycerides to alcohol, type and amount of catalyst, reaction temperature, reaction time, and free fatty acids and water content of vegetable oils or animal fats. The transesterification reaction proceeds with or without a catalyst by using primary or secondary monohydric aliphatic alcohols having 1–8 carbon atoms as follows:

Generally, the reaction temperature near the boiling point of the alcohol is recommended. The reactions take place at low temperatures (approximately 65°C, 160°F) and at modest pressures (2 atm, 1 atm = 14.7 psi). Biodiesel is further purified by washing and evaporation to remove any remaining methanol. The oil (87%), alcohol (9%), and

catalyst (1%) are the inputs in the production of biodiesel (86%), the main output. Pretreatment is not required if the reaction is carried out under high pressure (9,000 kPa) and high temperature (240°C, 465°F), where simultaneous esterification and transesterification take place with maximum yield obtained at temperatures ranging from 60 to 80°C (140 to 175°F) at a molar ratio of 6:1. The alcohols employed in the transesterification are generally short chain alcohols such as methanol, ethanol, propanol, and butanol. It was reported that when transesterification of soybean oil using methanol, ethanol, and butanol was performed, 96–98% of ester could be obtained after 1 hour.

Biodiesel – Transesterification, Catalytic

Transesterification reactions can be catalyzed by *alkalis* or *enzymes*. The catalytic transesterification of vegetable oils with methanol is an important industrial method used in biodiesel synthesis. Also known as methanolysis, this reaction is well established using acids or alkalis, such as sulfuric acid or sodium hydroxide as catalysts. However, these catalytic systems are less active or completely inactive for long chain alcohols. Usually, industries use sodium or potassium hydroxide or sodium or potassium methoxide as catalyst since they are relatively cheap and quite active for this reaction. Enzyme-catalyzed procedures, using lipase as catalyst, do not produce side reactions, but the lipases are expensive for industrial-scale production and a three-step process was required to achieve a 95% conversion. The acid-catalyzed process (Table B-7) is useful when a high amount of free acids is present in the vegetable oil, but the reaction time is on the order of 48 to 96 hours, even at the boiling point of the alcohol, and a high molar ratio of alcohol was needed (20:1 wt/wt to the oil).

Table B-7 Schematic of the catalytic transesterification process for biodiesel production.

Feedstock	Reactor	Products
Vegetable oil	Catalyst	Biodiesel
Methanol*		Glycerol

*Ethanol may also be used.

The transesterification process is catalyzed by alkaline metal alkoxides, and hydroxides, as well as sodium or potassium carbonates. Alkali-catalyzed transesterification with short-chain alcohols, for example, generates high yields of methyl esters in short reaction times. The alkaline catalysts show high performance for obtaining vegetable oils with high quality, but a question often arises; that is, the oils contain significant amounts of free fatty acids which cannot be converted into biodiesels but to a lot of soap. These free fatty acids react with the alkaline catalyst to produce soaps that inhibit the separation of the biodiesel, glycerin, and wash water. Triglycerides are readily transesterified in a batch operation in the presence of alkaline catalyst at atmospheric pressure and at a temperature of approximately 60 to 70°C (140 to 160°F) with an excess of methanol. It often takes at least several hours to ensure the alkali (NaOH or KOH) catalytic transesterification reaction is complete. Moreover, removal of these catalysts is technically difficult and brings extra cost to the final product. Nevertheless, these methods are a good alternative since they can give the same high conversions of vegetable oils just by increasing the catalyst concentration to 1 or 2 mol%. Alkaline metal alkoxides (as CH_3ONa for the methanolysis) are the most active catalysts since they give high yields (> 98%) in short reaction times (30 min) even if they are applied at low molar concentrations (0.5 mol%).

The transesterification process is catalyzed by sulfuric, hydrochloric, and organic sulfonic acids. In general, acid-catalyzed reactions are performed at high alcohol-to-oil molar ratios, low-to-moderate temperatures and pressures, and high acid catalyst concentrations. These catalysts give high yields in alkyl esters, but these reactions are slow, requiring typically temperature above 100°C (212°F) and more than 3 h to complete the conversion. Studies of the acid-catalyzed system have been limited in number. Despite the relatively slow reaction rate, the acid-catalyzed process offers benefits with respect to its independence from free fatty acid content and the consequent absence of a pretreatment step. These advantages favor the use of the acid-catalyzed process when using waste cooking oil as the raw material.

Enzyme-catalyzed reactions (such as lipase-catalyzed reactions) have advantages over traditional chemical-catalyzed reactions: the generation of no by-products, easy product recovery, mild reaction conditions, and catalyst

recycling. Also, enzymatic reactions are insensitive to free fatty acids and water content in waste cooking oil. As for the enzyme-catalyzed system, it requires a much longer reaction time than the other two systems. The enzyme reactions are highly specific and chemically clean. Because the alcohol can be inhibitory to the enzyme, a typical strategy is to feed the alcohol into the reactor in three steps of 1:1 mole ratio each. The reactions are slow, with a three-step sequence requiring from 4 to 40 hours, or more. The reaction conditions are modest, from 35 to 45°C (95 to 113°F). The main problem of the enzyme-catalyzed process is the high cost of the lipases used as catalyst.

Synthesis of biodiesel using enzymes such as *Candida antarctica*, *Candida rugosa*, *Pseudomonas cepacia*, *immobilized lipase (Lipozyme RMIM)*, *Pseudomonas* sp., and *Rhizomucor miehei* is well reported in the literature. In the previously mentioned work (Shah and Gupta, 2007), the best yield 98% (w/w) was obtained by using *Pseudomonas cepacia* lipase immobilized on celite at 50°C in the presence of 4–5% (w/w) water in 8 hours.

Biodiesel – Transesterification, Supercritical Methanol

The transesterification of triglycerides by supercritical methanol (SCM), ethanol, propanol, and butanol has proved to be the most promising process. Recently, a catalysts-free method was developed for biodiesel production by employing supercritical methanol (Saka and Kusdiana, 2001). The supercritical treatment at 350°C, 43 MPa, and 240 s with a molar ratio of 42 in methanol is the optimum condition for transesterification of rapeseed oil to biodiesel fuel (Kusdiana and Saka, 2004a).

To achieve more moderate reaction conditions, further effort was made through the two-step preparation. In this method, oils/fats are, first, treated in subcritical water for hydrolysis reaction to produce fatty acids. After hydrolysis, the reaction mixture is separated into oil phase and water phase by decantation. The oil phase (upper portion) is mainly fatty acids, while the water phase (lower portion) contains glycerol in water. The separated oil phase is then mixed with methanol and treated at supercritical condition to produce fatty acid methyl esters (FAMEs) thorough methyl esterification. After removing unreacted methanol and water produced in reaction, fatty acid methyl esters can be obtained as biodiesel. Therefore, in this process, methyl esterification is the main reaction for the formation of fatty acid methyl esters, while in the one-step method, transesterification is the major one.

Reaction by supercritical methanol has some advantages: (i) glycerides and free fatty acids are reacted with equivalent rates, (ii) the homogeneous phase eliminates diffusive problems, (iii) the process tolerates great percentages of water in the feedstock catalytic process and requires the periodical removal of water in the feedstock or in intermediate stage to prevent catalyst deactivation, (iv) the catalyst removal step is eliminated, and (v) if high methanol-to-oil ratios are used, total conversion of the oil can be achieved in a few minutes. Some disadvantages of the one-stage supercritical method are clear: (i) the method operates at high pressure, (ii) the high temperatures bring along proportionally high heating and cooling costs, (iii) high methanol-to-oil ratio (usually set at 42) involves high costs for the evaporation of the unreacted methanol, and (iv) the process as posed to date does not explain how to reduce free glycerol to less than 0.02% as established in the ASTM D6584 or other equivalent international standards.

Biodiesel – Transesterification, Reaction Parameters

The main factors affecting transesterification are the molar ratio of glycerides to alcohol, catalyst, reaction temperature and pressure, reaction time, and the contents of free fatty acids and water in oils.

The free fatty acids and moisture content are key parameters for determining the viability of the vegetable oil transesterification process. In the transesterification, free fatty acids and water always produce negative effects, since the presence of free fatty acids and water causes soap formation, consumes catalyst, and reduces catalyst effectiveness, all of which result in a low conversion. These free fatty acids react with the alkaline catalyst to produce soaps that inhibit the separation of the biodiesel, glycerin, and wash water. To carry the base catalyzed reaction to completion, a free fatty acid value lower than 3% is needed.

The presence of water has a greater negative effect on transesterification than that of the free fatty acids. In the transesterification of beef tallow catalyzed by sodium hydroxide (NaOH) in presence of free fatty acids and water, the water and free fatty acid contents must be maintained at specified levels.

The effect of reaction temperature on production of propyl oleate was examined at the temperature range from 40°C to 70°C with free *P. fluorescens* lipase (Iso et al., 2001). The conversion ratio to propyl oleate was observed highest at 60°C (140°F), whereas the activity highly decreased at 70°C (158°F).

The conversion rate increases with reaction time. The transesterification of rice bran oil with methanol was studied at molar ratios of 4:1, 5:1, and 6:1. At molar ratios of 4:1 and 5:1, there was significant increase in yield when the reaction time was increased from 4 to 6 h. Among the three molar ratios studied, ratio 6:1 gave the best results.

One of the most important factors that affect the yield of ester is the molar ratio of alcohol to triglyceride. Although the stoichiometric molar ratio of methanol to triglyceride for transesterification is 3:1, higher molar ratios are used to enhance the solubility and to increase the contact between the triglyceride and alcohol molecules. In addition, investigation of the effect of molar ratio on the transesterification of sunflower oil with methanol showed that when the molar ratio varied from 6:1 to 1:1 and concluded that 98% conversion to ester was obtained at a molar ratio of 6:1. Another important variable affecting the yield of methyl ester is the type of alcohol to triglyceride. In general, short chain alcohols such as methanol, ethanol, propanol, and butanol can be used in the transesterification reaction to obtain high methyl ester yields.

Catalysts used for the transesterification of triglycerides are classified as alkali, acid, and enzyme. Alkali-catalyzed transesterification is much faster than acid-catalyzed transesterification and is most often used commercially and, quite often, for the base-catalyzed transesterification, the best yields were obtained when the catalyst was used in small concentration, i.e., 0.5% wt/wt of oil. On the other hand, during the production of free and bound ethyl ester (FAEE) from castor oil, hydrochloric acid is much more effective than sodium hydroxide

Bioenergy

Bioenergy is renewable energy produced from organic matter – the conversion of the complex carbohydrates in organic matter to energy; organic matter may either be used directly as a fuel, processed into liquids and gasses, or be a residual of processing and conversion. Bioenergy (although not quite correct) is often used interchangeably with, biofuel and biomass. More typically, the term bioenergy refers to electricity and gas that is generated from biomass, which can be any form of plants and timber to agricultural and food waste – and even sewage. The term bioenergy also covers transport fuel (biofuel) produced from organic matter.

Biofuel is fuel derived from biological sources and biomass is the biological material used as a biofuel, as well as the social, economic, scientific, and technical fields associated with using biological sources for energy. In reality, bioenergy is the energy extracted from the biomass, as the biomass is the fuel and the bioenergy is the energy contained in the fuel.

The terms bioenergy and renewable energy are often (incorrectly used) interchangeably. However, bioenergy is specific and refers to energy produced from biological course (i.e., biomass). On the other hand, renewable energy is a more collective term that includes not only bioenergy but also nuclear energy, solar energy, tidal energy, and wind energy.

Bioenergy can offer renewable, low-carbon energy systems, sequestering atmospheric carbon as well as offer numerous environmental and socioeconomic benefits and therefore supporting global climate change targets and wider environmental, social, economic, and sustainable targets.

In addition, it is important to consider various sustainable aspects of bioenergy systems beyond carbon. Ensuring that bioenergy offers the required holistic emission reduction, context, specific and long-term approaches are necessary to understand synergies and the tradeoff of the bioenergy and related agricultural and forestry systems.

Bioenergy Crops

Bioenergy crops are low-cost and low-maintenance crops grown solely for energy production by (for example) combustion. The crops are processed into solid, liquid, or gaseous fuels, such as pellets, bioethanol, or biogas. The fuels are burned to generate electrical power or heat. The plants are generally categorized as woody or herbaceous. The former – woody plants include willow and poplar while the latter – herbaceous plants – include miscanthus and

these crops, while physically smaller than trees, store (approximately) twice the amount of carbon dioxide (in the form of carbon) below ground, compared to woody crops.

Thus, bioenergy crops include fast-growing trees such as hybrid poplar, black locust, willow, and silver maple in addition to annual crops such as corn, sweet sorghum, and perennial grasses such as switch grass. The first-generation bioenergy crops include corn, sorghum, rapeseed, and sugarcane, whereas the second-generation bioenergy crops are comprised of switchgrass, miscanthus, alfalfa, reed canary grass, Napier grass, and other plants.

Briefly, switch grass is a thin-stemmed, warm season, perennial grass that has shown high potential as a high yielding crop that can be readily grown in areas that are also suitable for crop production. In fact, there are many perennial crops (grass and tree species) that show high potential for production of cost-competitive cellulosic biomass. Switch grass can be viewed as a surrogate for many perennial energy crops when estimating biomass supply and availability.

Bioenergy crops increase soil carbon and fix atmospheric carbon. In addition, bioenergy crops (miscanthus, sorghum, and poplar) could also be used for the phytoremediation of heavy metal-contaminated soils. The bioenergy crops include specific plants that are grown and maintained at lower costs for biofuel production. Many other crops are possible, and the optimal crop will vary with growing season and other environmental factors. Most fast-growing woody and annual crops are high in hemicellulose sugars such as xylose.

See also: Bioenergy, Biofuel, Biomass.

Bioenergy System

A bioenergy system is an energy system which is comprised of a source which generates energy and modulates it in some manner such that it conveys energy. There is also a mechanism connecting the bioenergy source to a transfer medium and a transfer medium through which the bioenergy flows. There is a coupling mechanism connecting the transfer medium bioenergy sink and a terminal sink which includes a mechanism for the storage and use of the energy. The input and output coupling depend on properties of the source and the transfer medium, likewise for the sink.

To evaluate the performance of a bioenergy system, the entire chain from biomass production up to the end-use should be considered. A major criterion for comparing total bioenergy systems is the net energy yield per hectare. If this net yield is low, the amount of land needed for the net production of a certain amount of energy is high and vice versa. Since land is a scarce commodity, high net energy yields per hectare are favored. Also, the environmental impacts of a specific energy crop are a criterion for selection. Logically, another major criterion is the cost of the biomass per GJ produced (or per GJ of fossil energy replaced).

Biomass for energy conversion is usually considered as a local resource. With appropriate logistic systems, access to biomass can be improved over a large geographical area. In this study, life cycle inventory has been used as a method to investigate the environmental load of selected bioenergy transport chains. As a case study, chains starting in Sweden and ending in Holland have been investigated. Biomass originates from tree sections or forest residues, the latter upgraded to bales or pellets. The study is concentrated on production of electricity; hot cooling water is considered as a loss.

See also: Bioenergy, Bioenergy Crops, Biomass.

Bioethanol

Bioethanol is ethanol produced from biomass feedstocks, which includes ethanol produced from the fermentation of crops, such as corn, as well as cellulosic ethanol produced from woody plants or grasses. The resource base is gradually widening to cellulosic crops, and even wood. Such low-cost feedstock would result in a global increased production potential for low-cost ethanol.

Unlike crude oil, bioethanol is a form of renewable energy that can be produced from agricultural feedstocks. It can be made from various crops such as sugar cane, potato, and maize.

The long-term prospects of bioethanol, or any other biofuels such as methanol and biodiesel, depend on biomass availability. Concerns related to its production and use relate to the large amount of arable land required for crops,

as well as the energy and pollution balance of the whole cycle of ethanol production. The availability of bioethanol depends on future food demand and food patterns, other types of land use, and agricultural productivity.

See also: Alcohols, Bioethanol Production, Ethanol.

Bioethanol Production

Bioethanol can be produced from a variety of crops, although the traditional feedstocks for the production of ethanol are still starch crops like corn, wheat and cassava and from sugar crops like sugar cane and sugar beet.

The development of lignocellulosic technology has meant that not only high energy content starch and sugar crops can be used but also woody biomass or waste residues from forestry. This process requires an additional pre-treatment process of pulping and enzymes to break down the organic compounds.

Additional steps that may be taken in a biorefinery include the drying and pelletization of bagasse (the waste component of sugar cane after juice extraction) to produce a secondary product along with ethanol, which makes the plant more economically feasible. In addition to the production of fuel pellets, one can also produce feed for animals, which could be used locally thereby reducing carbon dioxide emissions from associated transport energy spent.

See also: Alcohols, Bioethanol.

Bioethers

Ethers are a class of carbon compounds that contain an ether group (C-O-C) in which either carbon may be attached to other carbon atoms as well (such as the commonly-used diethyl ether, $\text{CH}_3\text{CH}_2\text{OCH}_2\text{CH}_3$). The most commonly used fuel additive ethers are methyl-tertiary-butyl-ether (MTBE) and ethyl-tertiary-butyl-ether (ETBE).

Bioethers (Table B-8) are produced by the reaction of reactive iso-olefin derivatives, such as iso-butylene, with bioethanol, which is ethanol produced from bio-sources.

Table B-8 Examples of bioether derivatives used in fuels.

Ether	Use in fuels
Dimethyl ether (DME)	Alternative fuel for gasoline engines
Diethyl ether (DEE):	Used as an ignition improver for gasoline
	Possible alternative fuel for gasoline engines
Methyl tertiary-butyl ether (MTBE):	Additive for gasoline
Ethyl tert-butyl ether (ETBE):	Additive for gasoline
Tert-amyl methyl ether (TAME):	Additive for gasoline
Tert-amyl ethyl ether (TAEE):	Additive for gasoline
	Increases the solubility of ethanol in diesel

When added to gasoline, a bioether can make the gasoline burn cleanly and completely and enhance engine performance, while reducing engine wear and toxic exhaust emissions, as well as the amount of ground-level ozone.

Biofiltration

Traditional gas cleaning and air pollution control technologies for pollutant gases, such as adsorption, absorption, and combustion, were developed to treat high concentration waste gas streams associated with process emissions from stationary point sources. Although these technologies rely on established physico-chemical principles to achieve effective control of gaseous pollutants, in many cases, the control technique yields products which require further treatment before disposal or recycling of treatment materials. In the case of treatment of dilute waste gas streams, however, these traditional methods are relatively less effective, more expensive, and wasteful in terms of energy consumption and identification of alternative control measures is warranted. A suitable alternate air pollution control technology is biofiltration, which utilizes naturally occurring microorganisms supported on a stationary bed (filter) to continuously treat contaminants in a flowing waste gas stream.

Biofiltration by definition is the aerobic degradation of pollutants from (in the current context) a gas stream in the presence of a carrier media. The early development work on biofiltration technology concentrated on organic media, such as, peat, compost, and wood bark. In general terms, organic compounds are degraded to carbon dioxide and water, while inorganic compounds, such as sulfur compounds, are oxidized to form oxygenated derivatives. The formation of these acidic compounds can lead to a lowering of pH of the filtration media which in turn impacts on the performance of the system. Removal of the oxidized compound from the media is an important consideration in the design of biofiltration systems. Biofiltration, like many processes based on bio-treatment in the crude oil refining and gas processing industries, is successfully emerging as a reliable, low-cost option for a broad range of air treatment applications. It is now becoming apparent that biological treatment will play a far more significant role in achieving environmental control on air emissions.

In the biofiltration process, three types of bioreactor designs are usually considered: the biofilter, (ii) the biotrickling filter, and (iii) the bioscrubber. The main differences between these systems concern their design and mode of operation: microorganism conditioning, the nature of the fluid phase (gas or liquid), and the presence or absence of stationary solid phases. Nevertheless, gas stream desulfurization has been carried out by the biotrickling filter and the bioscrubber.

The biofilter is a pollution control technique which involves using a bioreactor that contains living material to capture and biologically degrade pollutants such as hydrogen sulfide. Common uses include processing wastewater, capturing harmful chemicals or silt from surface runoff, and the macrobiotic oxidation of contaminants in gas streams. The technology finds greatest application in treating malodorous compounds and water-soluble volatile organic compounds (VOCs). Compounds treated are typically mixed VOCs and various sulfur compounds, including hydrogen sulfide. Large airflows may be treated, although a large area (footprint) has typically been required. Engineered biofilters, designed and built since the early 1990s, have provided significant footprint reductions over the conventional flat-bed, organic media type.

In the process, the polluted gas flow is purified with biofiltration by conducting the gas flow upward through a filter bed, which consists of biological material, e.g., compost, tree bark, or peat. The filter material is a carrier of a thin water film in which microorganisms live. The pollutants in the gas flow is held back by adsorption and/or absorption on the filter material, and then decomposed by present microorganisms. The filter material serves as a supplier of necessary nutrients. The products of the conversion are carbon dioxide, sulfate, and nitrate. The dry weight of the filter varies typically from 40 to 60 %. To reduce desiccation of the bed, the gas flow must be saturated with water. For this reason, polluted gas flow is moistened before it goes through the biofilter, which is achieved by using a pre-scrubber. The relative humidity of the gas must be 95%. In practice, it is always better to apply a moistener to protect the biofilter against dehydration.

A biotrickling filter is a packed bed bioreactor with immobilized biomass. The gas flows through a fixed bed co- or counter-currently to a mobile liquid phase. Synthetic carriers are usually used and these include plastic, ceramic, lava rocks, polyurethane foam, etc. The synthetic carrier does not provide any nutrients, so the liquid mobile phase must contain nutrients for the growth and maintenance of the biomass. Programmed or continuous discharge of

recirculation medium helps to remove the oxidation products. The hydrogen sulfide must be transferred from the gas to liquid phase, and the degradation is finally carried out in the biofilm.

According to the microbial cycling of sulfur, the biological oxidation of hydrogen sulfide to sulfate is one of the major reactions involved. There are numerous sulfur-oxidizing microorganisms, but hydrogen sulfide is exclusively oxidized by prokaryotes. In any case, the biotrickling filter is typically inoculated with aerobic active sludge, and during the process, a specific biomass population is developed.

A biotrickling filter can be operated under aerobic or anoxic conditions. The removal of hydrogen sulfide from the gas stream has been mainly studied under aerobic conditions, and the overall reaction is:

In summary, two compounds can be produced: sulfate and elemental sulfur, and the production ratio of sulfate (SO_4^{2-}) will be dependent on the oxygen-hydrogen sulfide ratio and the trickling liquid velocity. Air is used to supply oxygen and must, therefore, be supplied in excess. However, control of the air supply is an important issue for safety and operational reasons – the lower and upper explosive limits for methane in air are 5% v/v and 15% v/v, respectively.

On the other hand, the gas stream can be diluted (mainly by the nitrogen content in air) and undesired residual oxygen can be found in the outlet stream. Therefore, a high oxygen supply is a drawback because the calorific power is also decreased and, moreover, a lack of oxygen increases clogging problems caused by the formation of elemental sulfur. The gas stream dilution depends on the efficiency in the mass transfer and the concentration of hydrogen sulfide. An alternative to the direct supply of air mixed with the gas stream involves the use of venture-based devices to increase the oxygen mass transfer. However, the installation of an aerated liquid recirculation system could produce hydrogen sulfide stripping of the dissolved sulfide.

The anoxic biotrickling filter is based on dissimilatory nitrate reduction. Dissimilatory nitrate reduction is carried out by certain bacteria that can use nitrate and/or nitrite as electron acceptors instead of oxygen:

Complete denitrification vs. partial hydrogen sulfide oxidation

Complete denitrification vs. complete hydrogen sulfide oxidation

Partial denitrification vs. partial hydrogen sulfide oxidation

Partial denitrification vs. complete hydrogen sulfide oxidation

Biofuels

The term *biofuel* is a generic name for gaseous, liquid, or solid fuels that are not derived from fossil fuels or contain a proportion of non-fossil fuel. For the purposes of this text, the term alternate fuels is used to represent those fuels

that are produced from plant sources as well as from other sources such as the organic constituents' (predominantly biological in nature) municipal and industrial waste. Thus, biofuels are *bio-materials* that are produced made from renewable biological sources which are now contemplated as grown specifically for the purpose of providing useful heat upon combustion. Biofuels are produced from sources such as: corn, soybeans, flaxseed, rapeseed, sugarcane, palm oil, sugar beet raw sewage, food scraps, animal parts, and rice.

Biofuels are fuels derived from plant materials – entering the market, driven by factors such as oil price spikes and the need for increased energy security. Examples of solid biofuels include wood, sawdust, grass cuttings, domestic refuse, charcoal, agricultural waste, non-food energy crops, and dried manure. Biofuels are also known as non-conventional fuels or alternative fuels. Alternative fuels can be classified as any fuel that is not derived from conventional sources like natural gas, crude oil, and coal.

Other than biofuels, some more examples of alternative fuels are solar, wind and tidal power, hydrogen, air engine power, and non-conventional oil. Since mankind discovered fire, wood has been the first biofuel used for heating and cooking which has also been used to produce electricity, and liquid biofuel have been used in the automotive industry since its inception. Unlike fossil fuels, which are necessarily derived from long deceased and metamorphosed biological organisms, biofuels (otherwise known as agrofuels) are obtained from only recently deceased or from living biological organisms, or in other words, derived from biomass or bio-waste.

When raw biomass is already in a suitable form (such as firewood), it can be combusted directly in a stove or furnace to provide heat or (industrially) to raise steam. When raw biomass is in an inconvenient form (such as sawdust, wood chips, grass, urban waste wood, and agricultural residues), the typical process is to densify the biomass. This process includes grinding the raw biomass to an appropriate particulate size, which depending on the densification type can be from 0.5 to 1.5 in., which is then concentrated into a fuel product. The current types of processes are pellet, cube, or puck. The pellet process is most common in Europe and is typically a pure wood product. The other types of densification are larger in size compared to a pellet and are compatible with a broad range of input feedstocks. The resulting densified fuel is easier transport and feed into thermal generation systems such as boilers.

Bioprocessing routes have a number of compelling advantages over conventional petrochemicals production (Table B-9). However, it is only in the last decade that rapid progress in biotechnology has facilitated the commercialization of a number of plant-based chemical processes.

Table B-9 Example of sources and use of biomass for energy products.

Resources	Collection	Conversion	Products
Agricultural crops	Harvesting	Biochemical	Biodiesel
Energy crops	Collection	Thermochemical	Heat
Forestry crops		Physical processes	Electrical power
Herbaceous biomass		Chemical Processes	Other fuels
Oil-bearing plants			
Wastes			
Woody biomass			

It is widely recognized that further significant production of plant-based chemicals will only be economically viable in highly integrated and efficient production complexes producing a diverse range of chemical products. Also contrasting with fossil fuels, biofuels do not contribute to the stock of total carbon dioxide in the atmosphere, since the sources of many biofuels are plants which normally remove carbon dioxide from the atmosphere, and then give off the same amount when burned and are, therefore, considered to be carbon dioxide neutral, although some observers would doubt this balance as being the result of mathematical manipulation without taking into consideration other important and influential factors.

In any given location, the type of biofuel used will depend on, among other minor factors, the available natural resources and local energy needed for processing requirements. Some of the main reasons for the shifting of interest

from fossil fuels to biofuels are the rising prices of oil and increasing emissions of greenhouse gases, low barriers to entry of biofuels, and increasing government support. There is also a requirement for the utilization of biofuels which is the reduction or total elimination of noxious emissions in an economical manner.

Biofuels can be classified into (i) first generation biofuels, (ii) second generation biofuels, and (iii) third generation biofuels, otherwise known as advanced biofuels, and the composition varies according to the feedstock and conversion techniques used. First-generation biofuels are derived from simple materials, such as mono and disaccharides (simple sugars), amylose and amylopectin (starch), esters of glycerol and fatty acids, free fatty acids and mono and diglycerides (fats and vegetable oils for biodiesel), methanol, ethanol, propanol and butanol (bioalcohols), methyl-tertiary-butyl-ether (or MTBE) and ethyl-tertiary-butyl-ether (or ethyl-t-butyl-ether, ETBE) – also known as bioether derivatives – methane, carbon-dioxide, nitrogen, hydrogen, hydrogen sulfide, oxygen, carbon monoxide and hydrogen (synthesis gas, often referred to as syngas) and cellulose, hemicellulose derivatives and lignin (wood for solid biofuels). Second generation biofuels are typically produced by the biomass to liquid (BTL) technology and are fuels such as ethanol from lignocellulose, biohydrogen, and wood diesel. The third generation type of biofuel is a biofuel from algae otherwise known as oilgae. *Botryococcus braunii* and *Chlorella vulgaris*, as well as macroalgae (seaweed), are typically used to produce such biofuels.

In fact, the free fatty acid from non-edible oils can be mixed with crude oil-derived diesel fuel (up to 30% w/w of the non-edible oil with diesel) may be usable without having too much of an adverse effect on the properties and efficiency of the diesel fuel. However, it must be remembered that olefins in fuel (such as gasoline or diesel fuel) can often result in the form of gums that have an adverse effect on fuel flow and efficiency. This tendency can be mitigated if the fatty acids are modified to produce more suitable fuels (i.e., fuels that do not form gum products) that can act as a diesel substitute. One method involves cracking at high temperatures on certain metal oxide catalysts (decarboxylation), which yields hydrocarbon products that can be hydrogenated to the saturated hydrocarbon derivative (n-heptadecane, $C_{17}H_{36}$). Using linoleic acid as the example, the pyrolysis product is heptadecadiene which hydrogenates to heptadecane:

More generally, many food sources and plant crops are the main feedstock for biofuels, and as such, one must take into consideration the deleterious effects of biofuel production on the natural resources of any particular region. These feedstocks may enter into animal as well as human food chains, and as biofuel production has increased, there has been criticism for diverting food away from human consumption, which can lead to food shortages and increased food prices. While the demand for biofuels is directly correlated to the price of oil, other issues also arise such as deforestation, soil erosion, water usage, carbon emissions, and biofuel prices which complicate the food-vs-fuel debate with regard to energy balance and efficiency. Henceforth, while discussing the benefits of biofuels, the pitfalls must be kept apparent, before sustainable biofuel production can be realized.

In conclusion, biofuels are classed according to source and type. They are derived from forest, agricultural, or fishery products or municipal wastes, as well as from agro-industry, food industry, and food service by-products and wastes. They may be solid, such as fuelwood, charcoal and wood-pellets; liquid, such as ethanol, biodiesel and pyrolysis oils; or gaseous, such as biogas.

Biofuels - Classification

Put simply, a biofuel is a fuel that is produced through contemporary processes from a biological source (biomass) rather than a fuel produced by the geological processes involved in the formation of fossil fuels. In addition, the word biofuel is usually reserved for liquid or gaseous fuels, used for transportation. Biofuels can be produced from

plants (such as energy crops), or from agricultural, commercial, domestic, and/or industrial wastes (if the waste has a biological origin).

Renewable biofuel sources generally involve carbon fixation, such as those that occur in plants or in micro-algae through the process of photosynthesis. Furthermore, some observers argue that biofuel can be carbon-neutral because all biomass crops sequester carbon to a certain extent because all crops move carbon dioxide from above-ground circulation to below-ground storage in the roots and the surrounding soil. However, the simple proposal that biofuel is carbon-neutral requires that the total carbon sequestered by the root system of the energy crop must compensate for all the above-ground emissions which must include any emissions caused by direct or indirect land-use change. Many first generation biofuel projects are not carbon-neutral given these demands – in fact, some may even have higher total emissions of greenhouse gases than some fossil-based alternatives.

Generally, the classification of biofuels is related to the method of preparation which, in turn, is related to the starting material of the agent by which the biomass is converted to biofuels (Table B-10). For convenience, biofuels are generally classified as being (i) first generation biofuels, (ii) second generation biofuels, and (iii) third generation biofuels. Examples of solid biofuels include wood, sawdust, grass cuttings, domestic refuse, charcoal, agricultural waste, non-food energy crops, and dried manure.

Table B-10 General classification of biofuels.

1st level	2nd level	Brief definition
Woodfuels	Direct Woodfuels	Wood from forests, shrubs, and other trees
	Indirect Woodfuels	Solid biofuels produced from wood processing
	Recovered Woodfuels	Wood used directly or indirectly as fuel
	Wood-based fuels	Liquid and gaseous biofuels from woody biomass
Agrofuels	Fuel crops	Growing plants for the production of biofuels
	Agricultural by-products	By-products from crop
	Animal by-products	Primarily excreta from farm animals
	Agro-industrial by-products	Biomass as bagasse and rice husks

When raw biomass is already in a suitable form (such as firewood), it can burn directly in a stove or furnace to provide heat or raise steam. When raw biomass is in an inconvenient form (such as sawdust, wood chips, grass, urban waste wood, and agricultural residues), the typical process is to densify the biomass. This process includes grinding the raw biomass to an appropriate particulate size, which depending on the densification type can be from 1 to 3 cm, which is then concentrated into a fuel product. The current types of processes are pellet, cube, or puck. The pellet process is most common in Europe and is typically a pure wood product. The other types of densification are larger in size compared to a pellet and are compatible with a broad range of input feedstocks. The resulting densified fuel is easier to transport and feed into thermal generation systems such as boilers.

Raw biomass emits considerable amounts of pollutants such as particulate matter and polyaromatic hydrocarbon derivatives, (PAHs also known as polynuclear aromatic hydrocarbon derivative, PNAs, PAHs) during combustion. Nevertheless, biomass fuels appear to have significantly less impact on the environment than fuels based on fossil sources.

A derivative of solid biofuel is biochar, which is produced by biomass pyrolysis. Biochar made from agricultural waste can substitute for wood charcoal. As wood stock becomes scarce, this alternative fuel is gaining popularity.

In conclusion, biofuels are classed according to source and type. They are derived from forest, agricultural or fishery products, or municipal wastes, as well as from agro-industry, food industry, and food service by-products and wastes. They may be solid, such as fuelwood, charcoal, and wood-pellets; liquid, such as ethanol, biodiesel and pyrolysis oils; or gaseous, such as biogas. Table 10 gives the biofuel yields for different feedstocks and countries.

See also: Alcohols, Algae Fuel, Bioalcohol, Bioethanol, Biodiesel.

Biofuels - Feedstocks

Currently, there is a focus on biofuels made from crops, such as corn, sugar cane, and soybeans, for use as renewable energy sources. Though it may seem beneficial to use renewable plant materials for biofuel, the use of crop residues and other biomass for biofuels raises many concerns related to major environmental problems, including food shortages and serious destruction of vital soil resources. Tropical countries have the highest potential to produce biofuel crops: higher energy yields, better greenhouse gas (GHG) balance if properly produced, lower costs, and in some countries, large reserves of uncultivated cropland. Sugar cane and oil palm are the highest-yielding tropical biofuel crops and consequently provide the greatest carbon offsets. Industrialized countries with biofuels targets (such as the United States and the European Union countries) are unlikely to have the agricultural land base needed to meet their growing demand for current production of biofuels, which are largely produced from food and feed crops (e.g., maize, oil palm, rapeseed, soy).

Bioethanol feedstocks can be divided into three major groups: (i) sucrose-containing feedstocks, such as sugar cane, sugar beet, sweet sorghum, and fruits, (ii) starchy materials, such as corn, milo, wheat, rice, potatoes, cassava, sweet potatoes, and barley, and (iii) lignocellulosic biomass, such as wood, straw, and grasses). In the short term, the production of bioethanol as a vehicular fuel is almost entirely dependent on starch and sugars from existing food crops. The drawback in producing bioethanol from sugar or starch is that the feedstock tends to be expensive and demanded by other applications as well.

Sugarcane as a bio-fuel crop has much expanded in the last decade, yielding anhydrous bio-ethanol (gasoline additive) and hydrated bio-ethanol by fermentation and distillation of sugarcane juice and molasses. The yield of ethanol per hectare, is on the order of 7,000 L per hectare. Brazil is the largest single producer of sugarcane with approximately 31% of the global production and millions of hectares (1 ha = 2.47 ac) of sugarcane under cultivation. Brazilian bio-ethanol is less expensive than that produced in the United States from corn or in Europe from sugar beet, because of shorter processing times, lower labor costs, and lower transport costs and input costs.

Another type of feedstock, which can be used for bioethanol production, is starch-based materials. Starch is a high yield feedstock for bioethanol production, but its hydrolysis is required to produce bioethanol by fermentation. Starch is a biopolymer, defined as a homopolymer consisting of only one monomer, D-glucose. The starch-based bioethanol industry has been commercially viable for approximately 30 years; in that time, tremendous improvements have been made in enzyme efficiency, reducing process costs and time, and increasing bioethanol yields. This type of feedstock is the most utilized for bioethanol production in North America and Europe. Corn and wheat are mainly employed with these purposes. Corn-based bioethanol production in most of the countries assessed is limited, especially compared to the United States.

There is also interest in a large amount of studies regarding the utilization of lignocellulosic biomass as a feedstock for producing fuel ethanol is being carried out worldwide. For countries where the cultivation of energy crops is difficult, lignocellulosic materials are an attractive option for the production of biofuels. Lignocellulosic materials serve as a cheap and abundant feedstock, which is required to produce fuel ethanol from renewable resources at reasonable costs. Producing bioethanol from lignocellulosic materials may allay many of the environmental and food-versus-fuel concerns that are drawbacks of producing bioethanol from food crops like sugar or corn.

Biodiesel has been mainly produced from renewable oil crops such as soybean, rapeseed, mustard seed oil, sunflower oil, and jatropha as well as from recycled vegetable oils and animal fats. The benefits of biodiesel also depend on the type of oilseed used. Seeds of high oil content, such as sunflower (40 to 50% w/w oil), rapeseed (42 to 48% w/w oil), and soybean seeds (18 to w/w 20% oil) have gained much attention lately as renewable energy sources because of their relatively high yield per hectare.

Biodiesel from oil crops is being produced in increasing amounts as a clean-burning alternative fuel, but its production in large quantities is not sustainable. Microalgal biofuels are a viable alternative. Microalgae are photosynthetic microorganisms that convert sunlight, water, and carbon dioxide to algal biomass. Algae have the potential to dwarf all the other biodiesel feedstocks due to their efficiency in photosynthesizing solar energy into chemical energy. Many algae are exceedingly rich in oil, which can be converted to bio-diesel. In fact, the oil productivity of many microalgae often exceeds the best-producing oil crops. The oil content of some microalgae exceeds 80% of dry

weight of algae biomass. Oil levels on the order of 20 to 50% w/w are quite common, and microalgae with high oil productivities are desired for producing biodiesel.

Biofuels – First Generation

First-generation biofuels are biofuels produced from sugar, starch, vegetable oil, or animal fats using conventional technology. The oil is obtained using the conventional techniques of production. Some of the most popular types of first-generation biofuels are: biodiesel, vegetable oil, biogas, bioalcohols, and synthesis gas.

Biodiesel has a composition similar to fossil/mineral diesel except that components in biodiesel include animal fats and oils from soy, mustard, flax, and sunflower seeds. The oil or animal fat is reacted with an alcohol through a process called transesterification to create the fuel. Vegetable oil is most often used in the production of biofuels, but there are cases where straight vegetable oil is being used as a fuel.

Biogas is created when organic matter breaks down anaerobically (that means without any oxygen). It can be produced from gunk like manure, sewage, and municipal waste. Some types of biogas, such as landfill gas, contain something called volatile organic compounds that are restricted by environmental regulations. Synthesis gas (syngas) is a mix of carbon dioxide and hydrogen. It is created when biomass is combusted with a measured (limited) amount of oxygen. Syngas can be used to produce diesel and can also be converted into methane.

Bioalcohols are produced through the fermentation of starches and sugars. Ethanol is the most common bioalcohol, although there is also methanol, propanol, and butanol. Some bioalcohols can be used directly in gasoline-powered engines.

The basic feedstocks for the production of first-generation biofuels are often seeds or grains such as wheat, which yields starch that is fermented into bioethanol, or sunflower seeds, which are pressed to yield vegetable oil that can be used in biodiesel. These feedstocks could instead enter the animal or human food chain, and as the global population has increased, their use in producing biofuels has been criticized for diverting food away from the human food chain, leading to food shortages and price rises.

The most common first-generation biofuels are bioalcohols, biodiesel, biogas, and vegetable oil.

See also: Bioalcohols, Biodiesel, Biofuels From Synthesis Gas, Biofuels – Second Generation, Biofuels – Third Generation, Biogas, Methanol, Ethanol, Vegetable Oil.

Biofuels – From Synthesis Gas

Biomass can be converted into fuels and chemicals indirectly (by gasification to syngas followed by catalytic conversion to liquid fuels) or directly to a liquid product by thermochemical means. The process yields synthesis gas (syngas) composed primarily of hydrogen and carbon monoxide, also called biosyngas.

The production of high-quality syngas from biomass, which is later used as a feedstock for biomass-to-liquids (BTL) production, requires particular attention. This is due to the fact that the production of synthesis gas from biomass is indeed the novel component in the gas-to-liquids concept – obtaining syngas from fossil raw materials (natural gas and coal) is a relatively mature technology.

Gasification is actually thermal degradation of the feedstock in the presence of an externally supplied oxidizing (oxygen-containing) agent e.g., air, steam, oxygen. Various gasification concepts have been developed over the years, mainly for the purposes of power generation. However, efficient biomass-to-liquids production imposes completely different requirements for the composition of the gas. The reason is that in power generation, the gas is used as a fuel, while in biomass-to-liquids processing, it is used as a chemical feedstock to obtain other products. This difference has implications with respect to the purity and composition of the gas.

In contrast, for biomass-to-liquids production, the amount of carbon monoxide and hydrogen is only important (the larger the amount, the better), while the calorific value is irrelevant. The presence of other hydrocarbon derivatives and inert components should be avoided or at least kept as low as possible. This can be achieved in the following ways: (i) by adjusting the amount of the various constituents of the gas stream, (ii) choice of the oxidizing agent.

The amount of components other than carbon monoxide and hydrogen (primarily hydrocarbon derivatives) can be reduced via further transformation into carbon monoxide and hydrogen. This is, however, rather energy intensive and costly (two processes – gasification and transformation). As a result, the overall energy efficiency of syngas production and of biomass-to-liquids processing is also reduced, leading to higher production costs.

The amount of various components can be minimized via a more complete decomposition of biomass, thereby preventing the formation of undesirable components at the gasification step. The minimization of the content of various hydrocarbon derivatives is achieved by increasing temperatures in the gasifier, along with shortening the residence time of feedstocks inside the reactor. Because of this short residence time, the particle size of feedstocks should be small enough (in any case – smaller than in gasification for power generation) in order that complete and efficient gasification can occur.

In gasification for power generation, typically, air is employed as oxidizing agent, as it is indeed the cheapest among all possible oxidizing agents. However, the application of air results in large amounts of nitrogen in the product gas, since nitrogen is the main constituent of air. The presence of such large quantities of nitrogen in the product gas does not hamper (very much) power generation, but it does hamper biomass-to-liquids production. Removing this nitrogen via liquefaction under cryogenic temperatures is extremely energy intensive, reduces substantially the overall biomass-to-liquids energy efficiency and increases costs. Amongst other potential options (steam, carbon dioxide, oxygen), from a technical and economic point of view oxygen appears to be the most suitable oxidizing agent for biomass-to-liquids manufacturing. It is true that the oxygen-blown gasification implies additional costs compared to the air-blown gasification, because of the oxygen production. Nevertheless, the energy and financial cost of producing oxygen seems to be far lower than the renewable energy and financial cost of cleaning up the product gas from air-blown gasification from nitrogen. This is partly due to the fact that the production of high-purity oxygen (above 95% O₂) is a mature technology.

In principle, the larger the carbon and hydrogen content in raw materials, employed in gas-to-liquids processing, is, the easier and more efficient the carbon monoxide and hydrogen. Hence, the natural gas pathway is the most convenient one since natural gas is gaseous and contains virtually carbon and hydrogen only. Solid raw materials (biomass, coal) involve more processing, because first they have to be gasified and then the product gas should be cleaned up from other components such as nitrogen oxides (NO_x), sulfur oxides (SO_x), and particulate matter to the extent of getting as high as possible purity of syngas.

Two basic types of biomass raw material are distinguished, viz, woody material and herbaceous material. Currently, woody material accounts for approximately 50% of total world bioenergy potential. Another 20% is straw-like feedstock, obtained as a by-product from agriculture. The dedicated cultivation of straw-like energy crops could increase the herbaceous share up to 40%.

Biofuels – Liquid

Liquid biofuels, as their name suggests, are fuels derived from biomass and processed to produce a combustible liquid fuel. There are two main categories: (i) alcohol fuels, such as methanol and ethanol, and (ii) vegetable oils, which are derived from plant seeds, such as sunflower, sesame, linseed, and rapeseed.

Methanol is produced by a process of chemical conversion from any biomass with a moisture content of less than 60%. Potential feedstocks include forest and agricultural residues, wood, and various energy crops. As with ethanol, it can either be blended with gasoline to improve the octane rating of the fuel or used in its neat form. Both methanol and ethanol are often preferred fuels for racing cars.

Ethanol is the most widely used liquid biofuel and is produced by fermentation of sugars and starches or cellulosic biomass. Most commercial production of ethanol is from sugar cane or sugar beet, as starches and cellulosic biomass usually require expensive pre-treatment. Ethanol is used as a renewable energy fuel source as well as being used for manufacture of cosmetics, pharmaceuticals, and also for the production of alcoholic beverages.

Vegetable oils are used to produce biodiesel. The process of oil extraction from the biomass is carried out the same way as for extraction of edible oil from plants. There are many crops grown in rural areas of the developing world

which are suitable for oil production – sunflower, coconut, cotton seed, palm, rapeseed, soy bean, peanut, hemp, and more. Sunflower oil, for example, has an energy content approximately 85% that of diesel fuel.

There are two well-established technologies for oil extraction: (i) the screw press and (ii) solvent extraction. The simple screw press, which is a device for physically extracting the oil from the plant - this technology is well suited to small-scale production of oil as fuel or as foodstuff in rural areas. The press can be motor-driven or hand-operated. On the other hand, solvent extraction is a chemical process which requires large, sophisticated equipment. This method is more efficient - that is, it extracts a greater percentage of the oil from the plant - but is less suited to rural applications.

Biodiesel production is not complex – the vegetable oil is converted to a useable fuel by adding ethanol or methanol alcohol along with a catalyst to improve the reaction. Small amounts of potassium hydroxide or sodium hydroxide (commonly called lye or caustic soda, which is used in soap making) are used as the catalyst material. Glycerine separates out as the reaction takes place and sinks to the bottom of the container. This removes the component that gums up the engine so that a standard diesel engine can be used. The glycerine can be used as a degreasing soap or refined to make other products.

Biofuels – Platforms

The technical platform chosen for second-generation biofuel production will be determined in part by the characteristics of the biomass available for processing. The majority of terrestrial biomass available is typically derived from agricultural plants and from wood grown in forests, as well as from waste residues generated in the processing or use of these resources. Much of the biomass being used for first-generation biofuel production includes agricultural crops that are rich in sugars and starch. Because of the prevalence of these feedstocks, the majority of activity toward developing new products in the United States has focused on the bioconversion platform.

Bioconversion isolates sugars from biomass, which can then be processed into value-added products. Native sugars found in sugarcane and sugar beet can be easily derived from these plants, and refined in facilities that require the lowest level of capital input. Starch, a storage molecule which is a dominant component of cereal crops such as corn and wheat, is comprised wholly of glucose. Starch may be subjected to an additional processing in the form of an acid- or enzyme-catalyzed hydrolysis step to liberate glucose using a single family of enzymes, the amylases, which makes bioconversion relatively simple. Downstream processing of sugars includes traditional fermentation, which uses yeast to produce ethanol; other types of fermentation, including bacterial fermentation under aerobic and anaerobic conditions, can produce a variety of other products from the sugar stream.

Forest biomass or agricultural residues are almost completely comprised of lignocellulosic molecules (wood), a structural matrix that gives the tree or plant strength and form. This type of biomass is a prime feedstock for combustion, and indeed remains a major source of energy for the world. The thermochemical platform utilizes pyrolysis and gasification processes to recover heat energy as well as the gaseous components of wood, known as synthesis gas (or syngas) which can then be refined by the Fischer-Tropsch process into synthetic fuels such as hydrocarbon liquids, methanol, and ethanol.

Lignocellulose is a complex matrix combining cellulose, hemicellulose, and lignin, along with a variable level of extractives. Cellulose is comprised of glucose, a six-carbon sugar, while hemicellulose contains both five- and six-carbon sugars, including glucose, galactose, mannose, arabinose, and xylose. The presence of cellulose and hemicellulose therefore makes lignocellulose a potential candidate for bioconversion. The ability of the bioconversion platform to isolate these components was initially limited, as the wood matrix is naturally resistant to decomposition. Recent advances, however, have made this process more commercially viable. Costs remain higher than for starch-based bioconversion, but there is added potential for value-added products that can utilize the lignin component of the wood.

In order to incorporate all aspects of biofuel production, including the value of co-products and the potential of the industry to diversify their product offering, we employ the biorefinery concept. The biorefinery concept is important because it offers many potential environmental, economic, and security-related benefits to society. Biorefineries provide the option of co-producing high-value, low-volume products for niche markets together with

lower-value commodity products, such as industrial platform chemicals, fuels, or energy, which offsets the higher costs that are associated with processing lignocellulosic materials.

The two technological platforms being explored for the lignocellulose-based biorefinery are complementary. Each technological platform provides different intermediate products for further processing. It is the range of these intermediates that dictates the types of end products that are likely to be successful in a commercial sense.

Biofuels – Production

There is some concern related to the energy efficiency of biofuel production. Production of biofuels from raw materials requires energy (for farming, transport, and conversion to final product), and it is not clear what the overall efficiency of the process is. For some biofuels, the energy balance may even be negative.

Since vast amounts of raw material are needed for biofuel production, monocultures and intensive farming may become more popular, which may cause environmental damages and undo some of the progress made toward sustainable agriculture.

Biofuels – Properties, Variations with Source

The quality and composition of a biofuel depends on the source of the biomass/feedstock as well as the types of processing and conversion techniques utilized in its manufacture. Biomass feedstock composition ultimately decides the yield from the chemical or biochemical conversion processes, which in turn, affects the economics involved. There are many plant varieties which are used as biofuel sources - the geography, weather conditions, soil composition, and legislation of a location normally dictates what types are grown specifically for biofuel production. Ethanol, biodiesel, and butanol are the main types of commercially produced biofuels.

The soil organic matter content contributes greatly to the grain and stover, and hence carbohydrate content of maize plants. Lignin and cell-wall cross-linking also affect the ethanol production. Selection for reduced lignin and increased cellulose in stover can potentially be expected to increase mechanical strength as well as ethanol yield. Although pretreatment and enzyme hydrolysis constitute two of the more costly steps in cellulosic ethanol production, stover with reduced lignin may still need to be treated before being subjected to enzyme hydrolysis. It seems unlikely that the cost savings in pretreatment from reduced lignin can be fully realized because of an accompanying reduction in biomass. However, for ethanol production to be commercially viable, improvements must not only be made to the efficiency of ethanol production per unit dry mass, but also per unit land area.

Biomass feedstock composition ultimately decides the yield from the chemical or biochemical conversion processes, which in turn, affects the economics involved. There are many plant varieties which are used as biofuel sources - the geography, weather conditions, soil composition, and legislation of a location normally dictates what types are grown specifically for biofuel production. Ethanol, biodiesel, and butanol are the main types of commercially produced biofuels.

The soil organic matter content contributes greatly to the grain and stover, and hence carbohydrate content of maize plants. Lignin and cell-wall cross-linking also affects the ethanol production. Selection for reduced lignin content and increased cellulose content in stover can potentially be expected to increase mechanical strength as well as ethanol yield. Although pretreatment and enzyme hydrolysis constitute two of the more costly steps in cellulosic ethanol production, stover with reduced lignin may still need to be treated before being subjected to enzyme hydrolysis.

The production of biofuels from lingo-cellulosic feedstocks can be achieved through two very different processing routes which are (i) the biochemical route in which enzymes and other micro-organisms are used to convert cellulose and hemicellulose components of the feedstocks to sugars prior to their fermentation to produce ethanol and (ii) the thermochemical route in which pyrolysis and gasification technologies produce a synthesis gas (carbon

monoxide, CO, and hydrogen, H₂) from which a wide range of long chain biofuels, such as synthetic diesel or aviation fuel, can be reformed. One key difference between the biochemical and thermochemical routes is that lignin component is a residue of the enzymatic hydrolysis process and can be used for heat and power generation.

Genetics as well as environmental factors affect the chemical composition of the various parts of the plant, and it was found that husk, followed by rind and pith, has the highest sugar (glucan + xylan) content. The term glucan represents diverse glucose polymers that differ in the position of glycosidic bonds, which can be short or long, branched or unbranched, alpha or beta isomers, and soluble or insoluble. On the other hand, the term represents a group of hemicellulose derivatives.

The variation in the structure of the glucan derivatives and the xylan derivatives (Figure B-2) is due to differences in the amounts of the main chemical constituents of biomass (cellulose, hemicelluloses, and lignin, all of which have different uses) being present in different proportions in the various parts of the plant.

Figure B-2 Structure of xylan from hardwood.

The production of fuels from ligno-cellulosic feedstocks can be achieved through two different processing routes. These are (i) biochemical, whereby enzymes and other microorganisms are used to convert cellulose and hemicellulose components of the feedstocks to sugars prior to their fermentation to produce ethanol and (ii) the thermochemical route, where pyrolysis and gasification technologies produce a synthesis gas (carbon monoxide and hydrogen) from which a wide range of long chain biofuels, such as synthetic diesel or aviation fuel, can be reformed. In terms of the biochemical route, much remains to be done related to (i) improving feedstock characteristics, (ii) improving the efficiency of enzymes, and (iii) improving overall process integration. One key difference between the biochemical and thermochemical routes is that lignin component is a residue of the enzymatic hydrolysis process and can be used for heat and power generation.

In terms of the production of biodiesel, transesterification optimization is desired, which would depend on the chemical composition of alkyl esters of vegetable oils, animal fats, and cooking oil. Most common feedstocks possess fatty acid profiles consisting mainly of five C₁₆ and C₁₈ fatty acids, namely, palmitic (hexadecanoic), stearic (octadecanoic), oleic (9(Z)-octadecenoic), linoleic (9(Z),12(Z)-octadecadienoic), and linolenic (9(Z),12(Z),15(Z)-octadecatrienoic) acids, with the exception of a few oils such as coconut oil, which contains high amounts of saturated acids in the C₁₂ to C₁₆ range. Changing the fatty acid profile can be achieved by physical means, genetic modification of the feedstock, or use of alternative feedstocks with different fatty acid profiles, such as wood-derived fatty-acids and related compounds.

The production of biogas is essentially achieved by wastewater treatment facilities which use anaerobic digestion to reduce the organic content of sewage sludge and animal wastes. The variation in the composition of biogas will depend on the organic content of the biomass as well as the pretreatment and processing. In addition to the main components (methane and carbon dioxide), biogas can also contain a variety of contaminants and impurities, such as sulfur compounds (hydrogen sulfide, mercaptans), halogens, ammonia, and dust particles.

Concerning biodiesel production, transesterification optimization is desired, which would depend on the chemical composition of alkyl esters of vegetable oils, animal fats, and cooking oil. Most common feedstocks possess fatty acid profiles consisting mainly of five C₁₆ and C₁₈ fatty acids, namely, palmitic (hexadecanoic), stearic (octadecanoic), oleic (9(Z)-octadecenoic), linoleic (9(Z),12(Z)-octadecadienoic), and linolenic (9(Z),12(Z),15(Z)-octadecatrienoic) acids, with the exception of a few oils such as coconut oil, which contains high amounts of saturated acids in the C₁₂ to C₁₆ range or others. Changing the fatty acid profile can be achieved by physical means, genetic modification of

the feedstock, or use of alternative feedstocks with different fatty acid profiles, such as wood-derived fatty acids and related compounds.

Bio-oil can be used directly as fuel or can be fractionated to obtain purified hydrocarbon derivatives boiling in the range of gasoline and diesel fuel – analysis of waste fish oil has shown that the main composition of fatty acids is: $C_{16:0}$ (15.9% w/w), $C_{18:2}$ (20.9% w/w), $C_{18:1}$ (17.3% w/w), $C_{20:5}$ (5.1% w/w), $C_{20:1}$ (7.6% w/w), $C_{22:6}$ (4.3% w/w), and $C_{22:1}$ (10.4% w/w) – the first number in the carbon-related subscript is the chain length and the second number is the position of the double bond in the carbon chain. Other compounds were classified as paraffin derivatives (4.5% w/w), iso-paraffin derivatives (8.3% w/w), olefin derivatives (26.6% w/w), naphthene derivatives (6.1% w/w), and aromatic derivatives (16.9% w/w).

Tall oil is a dark, viscous, and odorous liquid that phase-separates from the used pulping liquor (alkaline black liquor) that remains after the pulping of wood chips, and contains sodium soaps of rosin and fatty acids. Fish oil is also a potentially good source of fatty acids for the production of bio-oil. In a particular study, waste fish oil was converted into bio-oil by a fast pyrolysis process at 525°C (975°F) in a continuous pilot plant reactor with a yield on the order of 72% yield. Many different chemical groups can be produced during the pyrolysis reaction, and the liquid product (bio-oil) obtained from triglyceride pyrolysis has a complex composition. This bio-oil can be used directly as fuel or can be fractionated to obtain purified hydrocarbon derivatives in the range of gasoline and diesel.

Green algae (aquatic and unicellular) biomass is also used in biodiesel production, and is an attractive source of triglycerides, as under good conditions, green algae can double its biomass in less than 24 hours. Factors such as carbon dioxide availability, sunlight, water, and space affect algal density, and the annual productivity and oil content of algae are far greater than seed crops.

One of the largest issues seems to be overall greenhouse gas emissions from the various biofuels when compared with crude oil fuels. To estimate the impacts of increases in renewable and alternative fuels on greenhouse gas emissions, the entire fuel lifecycle including fossil fuel extraction or feedstock growth, fuel production, distribution, and combustion should be taken into consideration to provide a comparison of the carbon dioxide emissions from different fuels.

It is generally accepted that biofuels have the potential to drastically lower carbon-dioxide emissions than fuels derived from crude oil, but in many instances, this is not the case. For example, ethanol made from corn requires a substantial amount of energy in terms of fertilization, irrigation, harvesting and fermentation processes and most of this energy comes from fossil fuels. As a result, some ethanol production scenarios emit more lifecycle carbon-dioxide emissions than gasoline. Cellulose-based ethanol, however, allows for more efficient and cost-effective fuel production, and the carbon footprint is decreased. Conversely, biodiesel blended into diesel at low levels reduces emissions of volatile organic compounds, carbon monoxide, particulate matter, and sulfur oxides during combustion. Further, over the full life cycle, biodiesel blends reduce carbon monoxide, particulate matter, and sulfur oxides compared with diesel.

The bulk density (related to energy density) of most solid biomass feedstocks is generally low, even after compression, and is approximately between 10 and 40% of the bulk density of most fossil fuels; however, liquid biofuels have comparable values. Since biomass materials are more reactive, with higher ignition stability, they are generally easier to gasify and thermochemically process into methanol and hydrogen (higher-value fuels). Coal ash may contain toxic metals and small amounts of other trace contaminants, while biomass ash may be used as a soil amendment to assist in replacing nutrients removed by harvest. Bioethanol possesses approximately 70% of the heating value of crude oil distillates, but its sulfur and ash contents are appreciably lower.

Ethanol has a lower energy density than gasoline, so for a given volume of gasoline, a larger volume of ethanol is needed to produce an equivalent amount of energy. Unfortunately, when ethanol is used to power vehicles, it leads to lower gas mileage, since energy density is correlated with gas mileage. Ethanol, which has approximately a 30% lower energy density than gasoline, contributes to a reduction in fuel mileage when it is mixed with gasoline, as now commonly practiced in the United States. Another problem with ethanol as an auto fuel is it is extremely hygroscopic. Ethanol is difficult to separate from water and readily absorbs water from its surrounding. This is a problem in the transport and storage of ethanol, as well as the purification of ethanol from water. Ethanol-containing fuels can easily absorb water, and decontamination (i.e., removal of water from fuel) is difficult. The difference between the properties of gasoline and ethanol also causes compatibility problems in engines. Biodiesel is the only alternative fuel to have fully completed the health effects testing requirements of the United States Clean Air Act.

The use of biodiesel in a conventional diesel engine results in substantial reduction of unburned hydrocarbon derivatives, carbon monoxide, and particulate matter compared to emissions from diesel fuel. In addition, the exhaust emissions of sulfur oxides and sulfates (major components of acid rain) from biodiesel are essentially eliminated compared to diesel. Of the major exhaust pollutants, both unburned hydrocarbon derivatives and nitrogen oxides are ozone or smog-forming precursors. The use of biodiesel results in a substantial reduction of unburned hydrocarbon derivatives. Emissions of nitrogen oxides are either slightly reduced or slightly increased depending on the duty cycle of the engine and testing methods used.

Based on engine testing, using the most stringent emissions testing protocols required by EPA for certification of fuels or fuel additives in the US, the overall ozone-forming potential of the speciated hydrocarbon emissions from biodiesel was nearly 50% less than that measured for diesel fuel. In a review published in 2009,⁴³ the environmental indicators related to biofuel production were examined.

The postulated superior properties of agrofuels when compared with fossil fuels, as we have seen, must be weighed very carefully among the various factors of cost, environmental impact, energy density, chemical composition and availability, and life cycle of food crops. No doubt, increasing advances in technology will tip the scales in favor of biofuels.

In terms of fuel properties, one of the largest issues seems to be overall greenhouse gas emissions from the various biofuels when compared with crude oil fuels. To estimate the impacts of increases in renewable and alternative fuels on greenhouse gas emissions, it is necessary to account for the entire fuel lifecycle including fossil fuel extraction or feedstock growth, fuel production, distribution, and combustion.

The fuels are compared on an energy equivalent or Btu basis. Thus, for instance, for every Btu of gasoline which is replaced by corn ethanol, the total lifecycle greenhouse gas emissions that would have been produced from that Btu of gasoline would be reduced by 21.8%. These emissions account not only for CO₂, but also methane and nitrous oxide.

It is generally accepted that biofuels have the potential to drastically lower carbon-dioxide emissions than fuels derived from crude oil, but in many instances, this is not the case. For example, ethanol made from corn requires a substantial amount of energy in fertilization, irrigation, harvesting, and fermentation processes and most of this energy comes from fossil fuels. As a result, some ethanol production scenarios emit more lifecycle carbon-dioxide emissions than gasoline. Cellulose-based ethanol, however, allows for more efficient and cost-effective fuel production, and the carbon footprint is decreased.

However, the use of biodiesel in a conventional diesel engine results in substantial reduction of unburned hydrocarbons, carbon monoxide, and particulate matter compared to emissions from diesel fuel. In addition, the exhaust emissions of sulfur oxides and sulfates (major components of acid rain) from biodiesel are essentially eliminated compared to diesel. Of the major exhaust pollutants, both unburned hydrocarbons and nitrogen oxides are ozone or smog-forming precursors. The use of biodiesel results in a substantial reduction of unburned hydrocarbons. Emissions of nitrogen oxides are either slightly reduced or slightly increased depending on the duty cycle of the engine and testing methods used.

The postulated superior properties of agrofuels when compared with fossil fuels, as we have seen, must be considered and compared very carefully among the various factors of cost, environmental impact, energy density, chemical composition, and availability and life cycle of food crops.

Biofuels – Second Generation

Second-generation biofuel production processes can use a variety of non-food crops. These include waste biomass, the stalks of wheat, corn, wood, and special-energy-or-biomass crops (e.g., *Miscanthus*). Second-generation biofuels use biomass-to-liquid technology, including cellulosic biofuels from non-food crops. Second-generation biofuels include biohydrogen, biomethanol, Fischer-Tropsch diesel, mixed alcohols, and wood diesel.

Second-generation biofuels (also called advanced biofuels) made from nonfood sources hold significant promise as a low-carbon, renewable transportation fuel that can complement traditional crude oil-based fuels in meeting the future energy needs of the world. Technologies that can convert cellulosic biomass, often regarded as a waste material, into transportation fuels are becoming popular. Examples of cellulosic biomass include: (i) agricultural wastes,

such as corn stalks and husks, (ii) forestry wastes, such as wood chips and tree trimmings, (iii) fast-growing trees and grasses grown as energy crops, (iv) waste paper, and (v) food processing wastes

Although using cellulosic biomass as a source of new transportation fuels has obvious advantages, these materials have different chemical structural bonds than food-based crops and are difficult to break down, especially on a large scale. These second-generation fuels may play an important role in diversifying the energy sources of the world and curbing greenhouse gas emissions.

Cellulosic ethanol production uses non-food crops or inedible waste products and does not divert food away from the animal or human food chain. Lignocellulose is the woody structural material of plants. This feedstock is abundant and diverse, and in some cases represents a significant disposal problem. The discovery of the fungus *Gliocladium roseum* points toward the production of so-called myco-diesel from cellulose. This organism was recently discovered in the rainforests of northern Patagonia and has the unique capability of converting cellulose into medium length hydrocarbon derivatives typically found in diesel fuel.

Biofuels – Specifications and Performance

ASTM International (ASTM), formally known as the American Society for testing materials, is an international organization which develops and publishes information on the technical standards of various products, materials, systems, and services. It is one of the largest and most highly regarded standards development organizations in the world. The available literature on the performance of biofuels when compared with traditional fossil fuels normally uses ASTM and ISO (International Standards Organization) specifications and parameters. The specifications provide details on requirements for fuel characteristics as well as the relevant standard test methods to use for each. The common international standard for biodiesel is EN 14214, while ASTM 6751 is most referenced in the United States. In Germany, the requirements for biodiesel are fixed in the DIN EN 14214 standard.

With regards to biodiesel, most of the world uses a system known as the “B” factor to state the amount of biodiesel in any fuel mix, in contrast to the “BA” or “E” system used for bioalcohol. Pure biodiesel is referred to as B100, while fuel containing 20% biodiesel is labeled B20.

The standards ensure that the following important factors in the fuel production process are satisfied: (i) complete reaction, (ii) removal of glycerin, (iii) removal of catalyst, (iv) removal of alcohol, and (v) ensuring the absence of free fatty acids. Basic industrial tests to determine whether the products conform to the standards typically include gas chromatography, a test that verifies only the more important of the variables above. Fuel meeting the quality standards is very non-toxic, with a toxicity rating (LD50) greater than 50 mL/kg.

One of the most important fuel properties of biodiesel and conventional diesel fuel derived from crude oil is viscosity, which is also an important property of lubricants. Ranges of acceptable kinematic viscosity are specified in various biodiesel and crude oil standards. Reducing viscosity is one of the main reasons why vegetable oils or fats are transesterified to biodiesel because the high viscosity of neat vegetable oils or fats ultimately leads to operational problems such as engine deposits. The viscosity of biodiesel is slightly greater than that of petrodiesel but approximately an order of magnitude less than that of the parent vegetable oil or fat. Biodiesel and its blends with petrodiesel display temperature-dependent viscosity similar to that of neat petrodiesel. Influencing factors are chain length, position, number and nature of double bonds, as well as the nature of the oxygenated moieties.

Classic biodiesel has a higher cloud point (temperature at which a fuel becomes hazy or cloudy and starts to gel) than petrodiesel. This makes its use impractical in cooler climates and limits its potential market. Other important chemical and physical properties described in ASTM standards for biodiesel are (i) total acid number, TAN, which indicates the presence of free fatty acids and carboxylic acids present, (ii) corrosion, which is the potential for copper corrosion, (iii) low temperature performance, which is described by the pour point and the cloud point, and (iv) oxidation stability.

In terms of the effects of biodiesel on fuel filters, use of biodiesel blends which do not meet up to the designated specifications, have shown to drastically reduce filter life. Blends greater than B20 may have enough of a solvent to break down the varnish deposits on the walls of existing fuel storage tanks or fuel systems. The breakdown of these varnish deposits will contaminate the fuel with particulate, which can cause fuel filters to plug rapidly.

Another disadvantage of biodiesel is that it tends to reduce fuel economy. Energy efficiency is the percentage of the fuel's thermal energy that is delivered as engine output, and biodiesel has shown no significant effect on the energy efficiency of any test engine. Volumetric efficiency, a measure that is more familiar to most vehicle users, is usually expressed as miles traveled per gallon of fuel (or kilometers per liter of fuel).

Approximately 11% of the weight of B100 is oxygen. The presence of oxygen in biodiesel improves combustion and therefore reduces hydrocarbon, carbon monoxide, and particulate emissions; but oxygenated fuels also tend to increase nitrogen oxide emissions. Engine tests have confirmed the expected increases and decreases of each exhaust component from engines without emission controls.

Areas of concern and interest are for the biofuels industry to have in place a good-quality control protocol for the measurement of bioalcohols, to avoid metal corrosion from water and acid corrosion (due to weak and strong acids and inorganic chlorides in solution). Also of importance are the limits set on phosphorous content (less than 5.0 mg/L in ethanol) to prevent engine catalyst deterioration, and copper content (less than 0.1 mg/kg), along with a sulfur content less than 10 mg/kg.

Up to a 10% blend level, the performance of bioethanol-blended petrol is similar to ordinary gasoline. At higher levels however, some engines may begin to exhibit problems, for example, stumbling under slight acceleration. The fuel also has more aggressive properties at higher concentrations of bioethanol which increases the possibility of deterioration of some components. Gasoline must be volatile enough to move from the carburetor or injectors into the cylinders and to vaporize prior to combustion. However, it can't be so volatile that it vaporizes and boils in the injectors, carburetor, fuel lines, or fuel pump, which could prevent it from being metered correctly. Also, if gasoline is too volatile, it evaporates into the air adding to environmental problems. There are a number of volatility specifications to ensure suppliers get this balancing act right. Adding bioethanol to gasoline as low-level blends increases the volatility of the blended fuel.

The Engine Fuel Specifications Regulations specify volatility measures for bioethanol-blended gasoline and gasoline. The limits for blends are similar to those for gasoline so as to ensure no changes in vehicles are required. Bioethanol introduces more oxygen into the fuel. In vehicles with simple fuel metering systems such as carburetors, this causes the mixture to become leaner which is advantageous for fuel economy and for lowering some types of exhaust emissions. However, it may cause some engines to stumble if they are already tuned reasonably lean. If a vehicle stumbles on bioethanol-blended gasoline, re-tuning should solve the problem. A vehicle tuned correctly for use on ordinary gasoline would normally not exhibit problems when using bioethanol blends.

The factors of availability, price, and independence of manufacturer, health benefits, engine improvements, and political implications must all be carefully weighed and assessed, before educated decisions can be made by the powers that be. It is hoped however, that despite some of the obvious setbacks of biofuel production, that it is still viewed as a step in the right direction, and emerging technologies and innovative ideas will encourage improvements in what is undoubtedly, the future of fuel.

Biofuels – Third Generation

Third-generation biofuels (also called advanced biofuels) seek to improve the feedstock, rather than improving the fuel-making process.

Designing oilier crops, for example, could greatly boost yield. Scientists have designed poplar trees with lower lignin content to make them easier to process. Researchers have already mapped the genomes of sorghum and corn, which may allow genetic agronomists to tweak the genes controlling oil production.

Algae fuel, also called oilgae or third-generation biofuel, is a biofuel from algae, which are low-input, high-yield feedstocks that can produce biofuels. Algae can produce up to 30 times more energy per acre than land crops such as soybeans. With the higher prices of fossil fuels, there is much interest in algaculture (farming algae).

One advantage of many biofuels over most other fuel types is that they are biodegradable, and so relatively harmless to the environment if spilled. Algae fuel still has its difficulties though, for instance, to produce algae fuels, it must be mixed uniformly, which, if done by agitation, could affect biomass growth. Algae, such as *Botryococcus braunii* and *Chlorella vulgaris*, are relatively easy to grow, but the algal oil is difficult to extract. Macroalgae (seaweed) also have a great potential for bioethanol and biogas production.

Recently, the term fourth-generation biofuels has arisen and is coming into popular use. Fourth-generation technology combines genetically optimized feedstocks, which are designed to capture large amounts of carbon, with genomically-synthesized microbes, which are made to efficiently make fuels. The key to the process is the capture and sequester of carbon dioxide, a process that renders fourth-generation biofuels a carbon negative source of fuel. However, the weak link is carbon capture and sequestration technology, which continues to challenge industry.

Biofuels – Use

Biomass has the potential to supply a considerable portion of the energy needs of the world, but the conversion of biomass to energy is carried out in an unsustainable manner that there are many negative environmental consequences. If biomass is to supply a greater proportion of the energy needs in the future, the challenge will be to produce biomass and to convert and use it without harming the natural environment. Technologies and processes exist which, if used correctly, make biomass-based fuels less harmful to the environment than fossil fuels. Applying these technologies and processes on a site-specific basis in order to minimize negative environmental impacts is a prerequisite for sustainable use of biomass energy in the future.

Biodiesel and bioethanol are widely used in automobiles and freight vehicles. For example, in Germany, most diesel fuel on sale at gas stations contains a few percent biodiesel, and many gas stations also sell 100% biodiesel. Some supermarket chains in the UK have switched to running their freight fleets on 50% biodiesel, and often include biofuels in the vehicle fuels they sell to consumers, and an increasing number of service stations are selling biodiesel blends (typically with 5% biodiesel).

In Europe, research is being undertaken into the use of biodiesel as domestic heating oil. A blend of 20% biodiesel with 80% kerosene (B20) has been tested successfully to power modern high efficiency condensing oil boilers. Boilers needed a preheat burner to prevent nozzle blockages and maintain clean combustion. Blends with a higher proportion of biodiesel were found to be less satisfactory, owing to the greater viscosity of biodiesel than conventional fuels when stored in fuel tanks outside the building at typical (non-arctic) winter temperatures.

See also: Biodiesel, Biofuels, Ethanol, Methanol.

Biogas

Biogas, which is also known as biomethane, landfill gas, swamp gas, and digester gas, is a collection of gases (largely methane and carbon dioxide) produced by the anaerobic degradation of biomass (non-fossil organic matter) by various bacteria (Table B-11).

Thus, biogas is a combustible gas derived from decomposing biological waste under anaerobic conditions. Biogas typically refers to a biofuel gas produced by anaerobic digestion or fermentation of organic matter including manure, sewage sludge, municipal solid waste, biodegradable waste, or any other biodegradable feedstock, under anaerobic conditions. Depending on where it is produced, biogas is also called swamp gas, marsh gas, landfill gas, and digester gas (Table B-9).

Table B-11 The composition of gas from various carbonaceous fuels.

Composition:	Digester gas	Landfill gas	Sewage gas	Agri-waste
Carbon Dioxide (CO ₂)	25-45%	35-50%	30-40%	25-45%
Methane (CH ₄)	45-65%	40-45%	55-65%	55-75%
Nitrogen (N ₂)	2-5%	0-20%	2-10%	0-10%

The primary component of biogas is methane gas, which comprises 50-90% by volume of biogas. Usually, biogas is 50% to 80% methane and 20% to 50% carbon dioxide, with the remainder trace gases such as hydrogen,

carbon monoxide, and nitrogen. Methane is also the primary component of natural gas, but natural gas is normally recovered with more than 70% methane, along with other hydrocarbons (such as butane and propane) and traces of carbon dioxide and other chemicals. Natural gas is processed so that it is almost entirely, 98%, methane. Biogas is produced in a variety of low-oxygen natural environments with degradable organic matter, including swamps, marshes, landfills, agricultural and other waste (sewage sludge, manure, waste lagoons), aquatic sediments, wet soils, buried organic matter, as well as via enteric fermentation in some animal digestive tracts, notably in cattle.

Biogas normally consists of 50 to 60% methane and has a variable composition and energy content (Btu/ft³) depending upon the source (Table B-12).

Table B-12 Energy content of various gases.

Coal seam gas (coalbed methane): 370-955 Btu/ft ³
Digester gas: 275-700 Btu/ft ³
Landfill gas: 275-700 Btu/ft ³
Manufactured gas (coal gas): 160-955 Btu/ft ³
Wood chip gas: 160-320 Btu/ft ³

Biogas is produced by means of a process known as anaerobic digestion – a process in which organic matter is broken down by microbiological activity in the absence of air. Biogas is generated from concentrations of sewage or manure. These are usually in the form of slurry comprised mostly of water (almost 95%). The slurry is fed into a digester, this input can be continuous (usually the case with sewage) or in batches. The digestion continues from approximately 10 days up to weeks. The temperature in the digester should be kept at 35°C (95°F), and although the digestion itself produces heat, in colder climates, heat may be necessary.

There are two common technologies for the production of biogas. The first involves the fermentation of human and/or animal waste in specially designed digesters:

Slurry → digester → biogas

The second is a more recently developed technology for capturing methane from municipal waste landfill sites. The scale of simple biogas plants can vary from a small household system to large commercial plants. The digestion of animal and human waste yields several benefits: (i) the production of methane for use as a fuel and (ii) the waste is reduced to slurry which has a high nutrient content which makes an ideal fertilizer, and in some cases, (iii) the fertilizer is the main product from the digester and the biogas is merely a by-product. During the digestion process, bacteria in the manure are killed, which is a great benefit to environmental health.

Two popular simple designs of digester have been developed: (i) the floating cover digester and (ii) fixed dome digester. The digestion process is the same in both digesters, but the gas collection method is different in each. In the floating cover digester, the water-sealed cover of the digester is capable of rising as gas is produced and acting as a storage chamber, whereas the fixed dome digester has a lower gas storage capacity and requires good sealing if gas leakage is to be prevented.

The waste fed into the digester undergoes digestion in the digestion chamber and the temperature of the process is quite critical – methane-producing bacteria operate most efficiently at temperatures between 30 and 40°C (86 to 104°F) or 50 and 60°C (122 to 140°F), and in colder climates, heat may have to be added to the chamber to encourage the bacteria to carry out their function. The product is a combination of methane and carbon dioxide, typically in the ratio of 6:4. Digestion time ranges from a week to months depending on the feedstock and the digestion temperature. The residual slurry is removed at the outlet and can be used as a fertilizer.

The composition of biogas varies depending upon the composition of the waste material in the landfill and the anaerobic digestion process. Landfill gas typically has methane concentrations around 50%. Advanced waste treatment technologies can produce biogas with 55 to 75% methane; often, air is introduced (5% by volume) for microbiological desulfurization. For example, the constituents (by volume) of biogas generally are methane (50 to 75%),

carbon dioxide (25 to 50%), nitrogen (0 to 10%), hydrogen (0 to 1%), hydrogen sulfide (0 to 3%), and oxygen (0 to 2%).

If biogas is cleaned up sufficiently, biogas has the same characteristics as natural gas. In this instance, the producer of the biogas can utilize the local gas distribution networks. The gas must be clean to reach pipeline quality. Water (H_2O), hydrogen sulfide (H_2S), and particulates are removed if present at high levels or if the gas is to be completely cleaned. Carbon dioxide is less frequently removed, but it must also be separated to achieve pipeline quality gas. If the gas is to be used without extensively cleaning, it is sometimes co-fired with natural gas to improve combustion. Biogas cleaned up to pipeline quality is called renewable natural gas and can be used in any application in which natural gas is used.

Current technology allows the gas to be recovered using sealed vessels and therefore available for heating, electrical generation, mechanical power, and so forth. Biogas can be retrieved from garbage or mechanical biological treatment waste processing systems. The solid by-product, digestate, can be used as a biofuel or a fertilizer. Like natural gas, biogas has a low volumetric energy density compared to liquid biofuels, but it can be purified to a natural gas equivalent and further compressed for use as a transportation fuel, substituting for natural gas. Methane is also suitable for use in fuel cell generators. Biogas is often made from wastes, but is also made from biomass energy feedstocks. Landfill gas cannot be distributed through utility natural gas pipelines unless it is cleaned up to less than 3% v/v carbon dioxide and several parts per million hydrogen sulfide, because these chemicals corrode the pipelines.

Biogas – Upgrading

Biogas upgrading principally refers to removal of the carbon dioxide from the biogas to increase energy density and decrease needed storage volumes of finished product. Moisture, sulfur compounds, organo-silicon compounds (siloxanes), and other impurities in biogas or fuel gas are usually removed as well to meet gas quality specifications, and because they can cause problems in gas handling equipment and damage engines and emissions controls. Biomethane from upgraded biogas or landfill gas can be compressed or liquefied and used as a fuel in compressed natural gas (CNG) or liquefied natural gas (LNG) vehicles.

Processes available for separating carbon dioxide from the methane in biogas include adsorption methods such as scrubbing with water, Selexol (polyethylene glycol ether), and amines, pressure swing absorption (PSA), membrane separation, and cryogenic separation. However, each biogas project is unique it can be a challenge to determine the best gas upgrading technology for the given situation. Digester biogas can have varying levels of carbon dioxide (CO_2) and elevated hydrogen sulfide (H_2S) to address. Landfill gas and gas from covered lagoon digesters can have elevated nitrogen (N_2) and oxygen (O_2) levels, and landfills and municipal wastewater treatment plant (WWTP) digesters have siloxanes that need to be handled.

Typically, biogas is usually fully saturated with water vapor and typically has from 40 to 60% methane (CH_4) and 40 to 60% v/v carbon dioxide (CO_2). Thus, the choice of an appropriate technology or combination of technologies to upgrade the gas from these modest methane levels up to 99% v/v methane can be challenging. The main treatment goal of gas upgrading projects is to get the carbon dioxide removed from the biogas stream to an acceptable level, typically on the order of with 1 to 2% v/v carbon dioxide. Actual specifications will vary based on end use and the specific requirements provided by the gas utility.

Selecting an upgrading system that can reliably meet the methane-oxygen-carbon dioxide-hydrogen sulfide specifications is critical for a successful relationship with one's gas off-taker. At times, such as at a new project site, technologies may need to be selected without having extensive biogas characterization data. Therefore, selecting a biogas upgrading system that can handle varying gas quality and quantity and stay within specifications is essential.

The preferred design approach is to design for existing biogas streams that allow for maximum data collection for the upfront characterization of the gas. Generally, gas is pretreated to remove water and hydrogen sulfide from the biogas stream before the gas the stream is fed to the upgrading process(es). Where appropriate, users should consider drying biogas through aggressive refrigeration techniques or desiccant drying. Hydrogen sulfide can be effectively removed by several techniques, including ferric chloride injection in the digester, chemical scrubbing, carbon filtration, iron-based media filtration, or biological desulfurization. Digester biogas and landfill gas containing traces

of siloxanes requires pretreatment through media filtration. In all cases, the pretreatment system needs to be evaluated to ensure that it does not interfere with the gas upgrading system.

In terms of water content, biogas from a digester has just emerged from a warm, liquid process so it is fully saturated with water. Water vapor, or steam, is dissolved in the gas to its highest degree possible, and thus the gas is extremely damp and humid, containing approximately 6 to 12% w/w water. Warm gas holds more water vapor than cool gas. Dew point is the measure used to describe the condition where steam starts to condense into liquid. High dew point (i.e., $>21^{\circ}\text{C}$, $>70^{\circ}\text{F}$) gas is indicative of very humid gas that is acceptable to send to wet upgrading systems. Low dew point (i.e., $<-29^{\circ}\text{C}$, $<-20^{\circ}\text{F}$) gas is indicative of very dry gas that is acceptable to send to dry upgrading systems. However, each of the upgrading systems is capable of meeting gas pipeline or vehicle fuel specifications, either as standalone units or in combination with each other.

There are four main technologies used to create the so-called renewable natural gas stream from biogas, and these are (i) membrane separation, (ii) pressure swing adsorption (PSA), (iii) amine scrubbing, and (iv) water wash, also known as water scrubbing. Typically, these processes are usually deployed individually but can sometimes be installed in a series with one another, as needed for the given project requirements.

The membrane system and the pressure swing adsorption system are somewhat similar as both are dry upgrading systems that involve a physical separation of the carbon dioxide and methane based on (i) molecular size, (ii) pressure, and (iii) ionic charge, if any. Water wash and amine systems are similar in that they are both wet upgrading systems and involve separating the carbon dioxide from the methane by solubilizing the carbon dioxide in a liquid solution while allowing the methane to remain in the gas phase.

Membrane Separation

The membrane separation technique uses polymeric membranes to separate the carbon dioxide from the methane in biogas while under high pressure. As a result of the process, there is (i) permeate gas, which is the gas that has traveled through the porous membrane and (ii) retentate gas, which is gas that is retained and collected at the end of the membrane fiber; this gas travelled down the path of the membrane lumen hole but did not travel through the porous membrane. In recent years, membrane manufacturers have improved manufacturing quality, improved membrane selectivity, and overall system methane recovery. These factors all lead to better overall system performance, improved economics, and increased opportunity for success.

For landfill gas or covered lagoon applications, separating nitrogen from methane is challenging with membranes; therefore, further gas polishing is required when there is a significant amount of nitrogen in the raw biogas. In addition, biogas oxygen levels can cause performance issues as membranes are not selective for separating oxygen. For example, sources of oxygen can be a less-than-airtight landfill or leaky covered lagoon, as well as leaking fittings on the suction side of compressing equipment.

A typical pretreatment option uses an activated carbon filter to remove hydrogen sulfide to a level <100 parts per million (ppm) and removal of volatile organic compounds (VOCs). Drying can be achieved by refrigerating the gas to 4 to 15°C (40 to 60°F) and capturing the resulting condensate. The volatile organic compounds should be free of any volatile organic compounds which can irreversibly foul or compromise some membrane types.

Pressure Swing Adsorption

The pressure swing adsorption (PSA) system is a batch process utilizing several vessels running in parallel under pressure. The heart of the process is an adsorptive medium, similar to activated carbon, which separates the constituents of the gas stream based on the molecular weight and size of the constituents. Predrying the gas ahead of the adsorbers to approximately 5°C (41°F) is required to keep the humidity out of the vessels to maximize their performance as dry adsorbers.

Carbon dioxide is preferentially adsorbed onto the media because it is a smaller molecule than methane and can permeate into the tiny pores in the carbon bed more easily and deeply. The methane goes through adsorber process columns relatively untouched, while the carbon dioxide does not. The adsorption process is reversible; thus, the carbon dioxide is eliminated during the regeneration cycle.

When a vessel has been saturated with contaminant gas, it is regenerated by reducing the pressure. At lower pressure, compounds are removed and desorbed from the media in a separate gas stream called "tail gas." The common cycle time to saturation is 2 to 4 minutes. The tail gas is a low-quality gas stream that contains the previously adsorbed

compound (such as carbon dioxide, hydrogen sulfide, and methane). Each vessel alternates its mode of operation from service, depressurization, regeneration, and finally repressurization before it returns to service mode.

Amine Scrubbing

The amine scrubbing system uses a two-step approach to upgrading biogas. The first step is adsorption followed by a second step of stripping or desorption. The amine portion of the scrubbing solvent molecule chemically reacts to the carbon dioxide in the biogas to retain it in solution. A common chemical deployed as the scrubbing solvent is monoethanolamine (MDEA). The methane fraction of the biogas passes through the packed tower reactor untouched by the scrubbing chemical. High methane purities can be achieved in the recovered natural gas (>99.9% v/v).

In the second step, the scrubbing solution is heated to boiling to reverse the chemical reaction. The carbon dioxide in the fully packed stripper tower is disassociated from the scrubbing solution and discharged. High carbon dioxide purity in the off-gas can be achieved to accommodate potential for reuse of the carbon dioxide. The regenerated amine scrubbing solution is then cooled and reused back in the scrubbing tower in a closed loop system. Systems run at a relatively low operating pressure of approximately 0.5 to 3 psi. This low-pressure design affords equipment and operational savings as compared to systems that run at high pressure. Raw biogas with a high content (>300 ppm) of hydrogen sulfide is recommended to be pretreated by any one of several desulfurization techniques.

The recovered methane is dehumidified through a desiccant dryer and then pressurized to supply the natural gas grid. Pressurization power consumption is lower than for systems that use gas compression ahead of the scrubbing system since just the recovered methane is compressed versus the total raw biogas flow in other systems.

Water Wash

The water wash system is a two-stage process much like amine systems. The first step is a high-pressure reactor column that works in a countercurrent fashion. Chilled water flows downward and biogas flows upward under high pressure (150 psig). Soluble gases such as carbon dioxide dissolve in the water. The second tower serves as a depressurization tower where pressure is released from the solution and carbon dioxide comes out of solution. Makeup water is added when needed. Blow-down water is purged from the system to maintain the desired pH and water quality.

This system is run as a wet process; thus, no predrying of the biogas is formally required but is recommended. Any hydrogen sulfide in the biogas stream is adsorbed in the process after which the hydrogen sulfide (H_2S) is purged from the system into the wastewater blow-down.

Biogenic Coal Bed Methane

All coals contain biogenic gas, but only the higher rank coal (bituminous) contains thermogenic gas. Biogenic methane is formed in coal seams by naturally occurring bacteria that are associated with meteoric water recharge at outcrop or sub-crop. Biogenic methane is a term used to describe natural gas derived from the reduction of carbon dioxide via biogeochemical processes. The processes which contribute to the production are complex, poorly understood, but pervasive in nature and vary from site to site. Biological processes include methanogenesis and hydrogenogenesis, but there are also geochemical processes that have been identified. Methanogenic bacteria generate methane by several pathways, principally the fermentation of acetate and the reduction of carbon dioxide. In coal seams, methanogens may increase coalbed methane production.

See also: Biogas.

Biogeochemical Cycles

A biogeochemical cycle (also called the substance turnover or cycling of substances) is a pathway by which a chemical substance moves through biotic compartments (the biosphere) and through abiotic compartments of the Earth (such as the atmosphere, the hydrosphere, and the lithosphere).

There are biogeochemical cycles for the chemical elements (such as calcium, carbon, hydrogen, mercury, nitrogen, oxygen, phosphorus, selenium, and sulfur) as well as ; molecular cycles for water and silica; macroscopic cycles such as the rock cycle as well as human-induced cycles for synthetic compounds such as polychlorinated biphenyl derivatives (PCBs). In some cycles, there are *reservoirs* where a substance remains for a long period of time.

The biogeochemical cycles operate at the global scale and involve all of the main components of the Earth system in which materials are transferred continually between the atmosphere, the aquasphere, and the geosphere. However, since the biogeochemical cycles involve elements that are essential for life, organisms play a vital part in those cycles. Typically then, the biogeochemical cycles involve an inorganic component (the abiotic part of the cycle, including sedimentary and atmospheric phases) and an organic component (comprising plants and animals, both living and dead). Like other environmental systems, biogeochemical cycles involve the flow of substances between stores (also known as reservoirs) in the geosphere, atmosphere, hydrosphere, and biosphere. Water plays a vital role in mediating many of the flows between stores. Three of the key biogeochemical cycles are the nitrogen, carbon, and sulfur cycles.

Finally, it must be noted that the biogeochemical cycles have been modified substantially by human activities which is necessary for consideration to understand the various environmental issues related to human activities.

Biohydrogen

Biohydrogen is hydrogen produced biologically (by biological process), most commonly by bacteria from waste organic materials.

Hydrogen (H_2) is not available independently in the atmosphere, but is always combined with other elements. Hence, before being used, it has to be extracted from various compounds, e.g., via the syngas route. Currently, hydrogen is produced mainly from natural gas and to a lesser extent from oil derivatives (totally 77% of all hydrogen production), while its production from biomass is new – due partly to the more sophisticated manufacturing of syngas from biomass compared to natural gas, but also to the much lower relative hydrogen content of biomass vice-versa natural gas.

Hydrogen can be produced from biomass by pyrolysis, gasification, steam gasification, steam-reforming of bio-oils, and enzymatic decomposition of sugars. The yield of hydrogen that can be produced from biomass is relatively low, 16 to 18% based on dry biomass weight. In the pyrolysis and gasification processes, water-gas shift is used to convert the reformed gas into hydrogen, and pressure swing adsorption is used to purify the product. Gasification coupled with water gas shift is the most widely practiced process route for biomass to hydrogen. In general, the gasification temperature is higher than that of pyrolysis and the yield of hydrogen from the gasification is higher than that of the pyrolysis. Modeling of biomass steam gasification to synthesis gas is a challenge because of the variability (composition, structure, reactivity, physical properties, etc.) of the raw material and because of the severe conditions (temperature, residence time, heating rate, etc.) required. Hydrogen can be produced via steam gasification of biomass materials. The yield of H_2 from steam gasification increases with increasing water-to-sample (W/S) ratio. The yields of hydrogen from steam gasification increase with increasing temperature.

Several concepts have promise for near-term to long-term process development for biohydrogen production. For example, the microbial shift reaction (analogous to one step of the steam methane reaction in coal gasification), operates at ambient temperatures in a single-stage process, compared to the two-stage, high-temperature, chemical catalyst processes currently used. Process development is just beginning, but this concept appears promising for near- to mid-term practical applications.

Hydrogen yields from the fermentation of organic wastes are typically less than 20% (on a heating value basis) compared to methane production. Higher yields might be possible at elevated temperatures, with nutrient limitations, and through metabolic engineering of the bacteria.

Photofermentation, the conversion of organic substrates to hydrogen by nitrogen-fixing photosynthetic bacteria, achieve high yields of hydrogen, but low solar conversion efficiencies. The inefficiency of the nitrogenase enzyme suggests that biohydrogen processes must be based on reversible hydrogenases.

Larger-scale biohydrogen production requires biophotolysis processes, such as hydrogen production from water and sunlight. Photobioreactor costs and solar conversion efficiencies are main challenges in the development of practical processes. Direct biophotolysis couples the reductant produced by photosynthesis directly to hydrogenase, producing oxygen and hydrogen simultaneously, while indirect processes separate these basically incompatible

reactions through intermediate carbon dioxide fixation. Direct, but not indirect, biophotolysis processes would require hydrogenase activity in the presence of high oxygen levels.

The photosynthetic production of hydrogen employs microorganisms such as cyanobacteria, which have been genetically modified to produce pure hydrogen rather than the metabolically relevant substances. The conversion efficiency from sunlight to hydrogen is small, usually under 0.1%, indicating the need for large collection areas. However, hydrogen build-up hinders further production and there has to be a continuous removal of the hydrogen produced, by pipelines to e.g., a shore location, where gas treatment and purification can take place.

Furthermore, if the bacteria are modified to produce maximum hydrogen, their own growth and reproduction are quenched. There presumably has to be a compromise made between the requirements of the organism and the amount of hydrogen produced for export, so that replacement of organisms (produced at some central biofactory) does not have to be made at frequent intervals.

Hybrid indirect processes using both algae and photosynthetic bacteria have been proposed and tested. The simplest indirect process would use the same algal cells for carbon dioxide fixation, oxygen evolution, and hydrogen production, at separate times or even in different reactors. The hydrogen reactions would take place both in the dark and light. Light-driven hydrogen evolution requires suppression of the oxygen evolution process. The biophotolysis process must achieve the highest possible solar conversion efficiencies, which will require development of algal strains with reduced light-harvesting pigment content.

Biological Action

Biological action is the action of biological organism on a substrate to produce a product, such as is envisioned in the production of biofuels by biological agents. In a scientific sense, a biological process is a method or means of changing one or more chemical reactions due to the activity of the biological agent which may result in a change in the composition of chemical(s) or material(s).

Although biological actions may involve only one step, often, multiple steps are involved. In the case of multiple steps, the steps may be sequential in time or sequential in space. Also, for a given amount of a feedstock, an expected amount of material can be determined at key steps in the process.

Thus, a biological process or bioconversion process involves the conversion of biomass into bioenergy, fertilizer, food, and chemicals through the biological action of microorganisms. One of the important biofuels obtained through bio-conversion is biogas (which is predominantly methane). In addition, and in the current context, biological processes are those processes that are vital for an organism to survive, and that shape the ability of the organism to interact with its environment. Biological processes involve many chemical reactions or other events that are involved in the persistence and transformation of life forms.

In contrast, the non-biological processes such as (a) direct combustion, (b) conversion of biomass into liquid fuels such as fuel oil (e.g., by pyrolysis - a type of fertilization, liquefaction, etc.), and (c) gasification.

Biological Alcohol

A biological alcohol is any alcohol that is provided through the action of a biological agent (such as a microbe, typically the biological agent is a colony of microbes) on a feedstock.

As an example, the fermentation process is a complex biochemical process during which yeast converts sugars to ethanol, carbon dioxide, and other metabolic by-products that contribute to the chemical composition and sensorial properties of the fermented foodstuffs. Control of the fermentation process is generally considered as a prerequisite to determine the quality of the final product. In this context, fermentation monitoring is a growing need, which calls for fast, low-cost, and nondestructive methods providing real-time or online information in order to assure an effective control at all stages of the process.

The production of the biological alcohol is accomplished by yeast, certain types of bacteria, as well as other microorganisms that result in the conversion of sugar derivatives into ethyl alcohol and carbon dioxide. In the process, yeast is mostly used as the biological agent and the yeast generally carries out the aerobic fermentation process, but it may also ferment the raw materials under anaerobic conditions. The process commences with the breakdown of sugars by yeasts to form pyruvate molecules (glycolysis) which, in the case of glucose, produces two molecules of pyruvic acid. The two molecules of pyruvic acid are then reduced to two molecules of ethanol and carbon dioxide.

Under anaerobic conditions, the pyruvate can be transformed to ethanol, where it first converts into an intermediate product (acetaldehyde, CH_3CHO) which further releases carbon dioxide and is converted into ethanol ($\text{CH}_3\text{CH}_2\text{OH}$).

See also: Bioalcohol, Bioethanol, Fermentation, Fermentation Chemistry.

Biological Conversion

Biological conversion (also referred to as biochemical conversion) involves breaking down biomass to make the carbohydrates available for processing into sugars, which can then be converted into biofuels and bioproducts through the use of microorganisms and catalysts. Potential fuel blend stocks and other bioproducts include the following: (i) renewable gasoline, (ii) ethanol and other alcohols, (iii) renewable chemical products, and (iv) renewable diesel.

Biochemical conversion uses biocatalysts, such as enzymes, in addition to heat and other chemicals, to convert the suitable portions of biomass (hemicellulose and cellulose) into an intermediate sugar stream. These sugars are intermediate building blocks that can then be fermented or chemically catalyzed into a range of advanced biofuels and value-added chemicals.

Bioconversion processes generally take place in bioreactors, which may be operated in batch, continuous, or semi-continuous mode, among others. Moreover, different bioreactor configurations may be suitable depending on the specific application. The technology may range from solid-phase bioconversion processes to gas-phase ones, besides aqueous phase bioprocesses. In any case, a given amount of moisture is generally needed, as this is required, in most cases, for optimal microbial activity. For any given feedstock, biocatalyst and bioreactor configuration and operating conditions will need to be optimized, in terms of aspects such as residence time in continuous processes, pH, or media composition (such as, for example, the carbon-nitrogen ratio).

Thus, bioconversion processes and biorefineries are environmentally friendly alternatives to common chemical processes and conventional oil refineries. They allow the production of a wide range of products with cheap biocatalysts, usually under mild conditions.

Biological Conversion – Aerobic Digestion

Aerobic digestion is the biochemical oxidative stabilization of wastewater sludge in open or closed tanks that are separate from the liquid process system. Aerobic digestion is a solids stabilization process that provides a limited supply of oxygen to microorganisms in order to facilitate oxidation of organic matter and convert it into carbon dioxide and water. The microorganisms utilized in aerobic digestion processes are mesophilic facultative bacteria which mean they thrive in temperatures between 20 and 37°C (68 and 100°F) and live under aerobic (presence of oxygen), anoxic (no

oxygen but with presence of nitrates), and anaerobic (no presence of oxygen or nitrates) conditions. Thus, the aerobic digester operates on the principle that as the food is depleted, the microbes, the endogenous phase, and the cell tissue are aerobically oxidized to carbon dioxide, water, ammonium ions (NH_4^+), nitrite ions (NO_2^-), and nitrate ions (NO_3^-).

In general, aerobic digestion is a relatively simple process; there are many design and operational parameters such as temperature control, oxygen transfer and mixing, nitrification and denitrification, solids retention time, pH control, sludge loading characteristics, and tank configuration that must be considered in order to achieve a sustainable process.

Typically, an aerobic digestion system consists of two or more aerated tanks used to process and store waste-activated sludge generated from the liquid treatment process and/or primary sludge from primary sedimentation tanks. The waste-activated sludge and primary sludge in an aerobic digestion system can be processed separately or can be combined into one product. Air is introduced to the tank(s) from an aeration system typically coarse or fine bubble diffuser equipment with the air being supplied by a positive displacement or centrifugal blower.

The bacteria continue metabolism as they do in the liquid process, but without new food, they use their own biomass (endogenous respiration). This stabilizes the sludge so that it is safer for human contact, does not attract vermin (vectors), and odors are reduced. This method of digestion is capable of handling waste-activated, trickling filter, or primary sludges as well as mixtures of the same.

Biological Conversion – Anaerobic Digestion

Anaerobic digestion is the decomposition of biological wastes by microorganisms, usually under wet conditions, in the absence of air (oxygen), to produce a gas comprising mostly methane and carbon dioxide. A digester system (the anaerobic digester) is a device that promotes the decomposition of manure or digestion of the organics in manure to simple organics and gaseous biogas products.

During anaerobic digestion of an organic material such as biomass, a varied mixture of complex compounds is converted to a very narrow range of simple compounds, mainly methane and carbon dioxide. The anaerobic bacteria are responsible for the biochemical transformation of the biodegradable organic fraction (BOF). The AD of organic material basically consists of hydrolysis, acidogenesis, acetogenesis, and methanogenesis. These transformations are involved in the breakdown of complex polymers, such as cellulose, fats, and proteins to long and short chain fatty acids, and finally to methane, carbon dioxide, and water.

Any organic substance can become subject to anaerobic digestion so long as there are warm, wet, and airless conditions. For example, marsh gas is a product of the anaerobic digestion of vegetation at the bottom of ponds; this gas rises to the surface and bubbles, and the gas is also combustible. With the aid of human intervention, there are two products of this process, biogas and landfill gas. The chemical processes behind the production of these gases are complex.

The anaerobic digestion process focuses on hastening the natural process of biomass conversion to a gaseous fuel (biogas). Research has been conducted to ascertain optimal conditions for anaerobic digestion. These include (i) the feedstock, (ii) the nutrients, (iii) the temperature, (iv) the moisture content of the feedstock, (v) the pH of the system, and (vi) the atmospheric conditions. Most of the biomass waste feedstocks (municipal solid waste, agricultural waste, farm waste, crop waste, and forestry waste) studied have produced a biogas rich in methane. This medium to high Btu gas can, in some instances, be upgraded to a substitute natural gas (SNG). Depending on the feedstock, sulfur may also be produced.

Anaerobic digestion is a multi-stage biological waste treatment process whereby bacteria, in the absence of oxygen, decompose organic matter to carbon dioxide, methane, and water. In this way, the waste sludge is stabilized and the obnoxious odor is removed. The process can, however, be described adequately and simply as occurring in two stages, involving two different types of bacteria. The process occurs in the absence of air; the decomposition in this case is caused not by heat but by bacterial action. In the first stage, the organic material present in the feed sludge is converted into organic acids (also called volatile fatty acids) by acid-forming bacteria. In the second stage, these organic acids serve as the substrate (food) for the strictly anaerobic methane-producing bacteria, which converts the acids into methane and carbon dioxide. The end result of the process is a well-established sludge in which 40 to 60% of the volatile solids are destroyed. Finally, a combustible gas is produced consisting of 60 to 75% methane and the remainder largely being carbon dioxide.

The anaerobic digestion process is a multi-stage biological waste treatment process whereby bacteria, in the absence of oxygen, decompose organic matter to carbon dioxide, methane and water. In this way, the waste sludge is stabilized and the obnoxious odor is removed. The process can, however be described adequately and simply as

occurring in two stages, involving two different types of bacteria. In the first stage, the organic material present in the feed sludge is converted into organic acids (also called volatile fatty acids) by acid-forming bacteria. In the second stage, these organic acids serve as the substrate (food) for the strictly anaerobic methane-producing bacteria, which converts the acids into methane and carbon dioxide. The end result of the process is a well-established sludge in which 40 to 60% v/v of the solids are consumed by the process. Finally, a combustible gas consisting of approximately 60 to 75% v/v methane is produced with the remainder being predominantly carbon dioxide.

Anaerobic digestion is a complex process which requires strict anaerobic conditions [oxidation reduction potential (ORP) < -200 mV] to proceed and depends on the coordinated activity of a complex microbial association to transform organic material into mostly carbon dioxide and methane. Despite the successive steps, hydrolysis is generally considered as rate limiting. The hydrolysis step degrades both insoluble organic material and high molecular weight compounds (lipids, polysaccharides, proteins, and nucleic acids) into soluble organic substances (amino acids and fatty acids). The components formed during hydrolysis are further split during acidogenesis, the second step.

Volatile fatty acids (VFAs) are produced by acidogenic bacteria along with ammonia (NH₃), carbon dioxide (CO₂), hydrogen sulfide (H₂S), and other by-products. The 3rd stage in anaerobic digestion is acetogenesis, where the higher organic acids and alcohols produced by acidogenesis are further digested by acetogens to produce mainly acetic acid and as well as carbon dioxide and hydrogen. The final stage of methanogenesis produces methane by two groups of methanogenic bacteria: (i) the first group splits acetate into methane and carbon dioxide and (ii) the second group uses hydrogen as an electron donor and carbon dioxide as the acceptor to produce methane. Thus:

The digestion process is continuous – fresh feedstock must be added continuously or at pre-determined frequent intervals. The gas formed during digestion is removed continuously. In high-rate digestion, stabilized sludge is displaced from the digester during feeding. In low-rate digestion, supernatant sludge is typically removed as the feed sludge is added; stabilized sludge is removed at less frequent intervals.

In a typical anaerobic digestion process, biomass is simply allowed to degrade in an anaerobic environment. A number of factors affect the entire process. They include (i) the temperature of the substrate, (ii) the loading rate, (iii) the pH, (iv) the residence time, (v) the concentration of nutrients, and (vi) the presence of any toxic substances.

In terms of temperature, the optimal temperature (where digestion and gasification proceeds at the highest rate) is 35°C (95°F). Below 15°C (59°F), the rate is so slow that little gas is produced. Temperature is also dependent on the bacterial populations: mesophilic or thermophilic. Mesophilic bacteria prefer temperatures ranging from 30 to 40°C. Thermophilic bacteria prefer temperatures ranging from 50 to 60°C (140°F).

The loading rate is the amount of fermentable matter that is fed into the digester per cubic meter of digester capacity. Any change in loading rate affects the balance inside the digester, so it should be kept constant. For a given capacity, if the loading rate is increased, the fermentation period is correspondingly increased. The common range of solid concentration is 7 to 9%, and digression from this range can cause fermentation to be retarded. In terms of the alkalinity/acidity (pH), the optimal gas formation occurs at pH of 7 to 8. If the pH becomes too acidic, gas production could stop altogether.

The retention time is the amount of time fermentable material resides inside the digester. It has been observed that maximum gas production takes place within the first four weeks, and then gradually tapers off. Detention time can be significantly reduced if the temperature is raised or the contents of the digester are agitated, or the supply of nutrients in the digester is augmented. Usually, some type of nutrient source is needed to help stimulate gas production. Bacteria use nitrogen, phosphorus, and potassium for their nutrients. Once these are available, fermentation proceeds very quickly. However, caution is advised that, although rare, toxic substances such as copper can inhibit gas production if found in large quantities.

It is essential that the organic acids formed in the first stage of the waste treatment process are converted to methane at the same rate at which they are formed. If not, they accumulate and ultimately lower the pH, leading to inhibition of the second stage of the digestion process and digester failure. The temperature must be maintained within certain ranges - heating increases the activity of the anaerobic bacteria reducing the required digestion time.

A pH of 7.0 to 7.5 is recommended to encourage the methane-producing stage. A correctly operating digester will have sufficient buffer capacity (alkalinity) introduced from the breakdown of organic matter. Also, the gas leaving the digester is almost saturated with water vapor which condenses as the gas stream cools there causing problems – the problem is more severe when digesters are heated. To mitigate the problem, it is essential to remove as much of the moisture as possible before the gas comes into contact with the gas system devices. For this reason, water traps should be located as close to the digester as possible and all piping should be sloped a minimum of 1% toward the water trap, which should be situated at a low point in the gas line.

Several types of digesters have been developed including the floating drum, the fixed dome, the bag, the plastic tube, the plug flow, and the up-flow anaerobic sludge blanket digesters. A digester is an airtight vessel or enclosure in which bacteria decomposes biomass in water to produce biogas. Both batch and continuous digesters are commercially available. While batch systems may be suitable for some applications, they are labor intensive, and in developed countries are probably not appropriate to the steady production of gas on any significant scale.

Mixing may be used in both batch and continuous digesters to enhance contact between the bacteria and substrate. It has, however, been argued that while mixing may increase conversion rates, it is not energy efficient. In two-stage systems, only the first stage is mixed. Multistage systems provide optimum conditions for the successive digestive steps, and further development may prove them to be economical for some biomass materials.

In a process of manure and straw mixture digestion, for the first 72 hours, the yield of methane was minimal (essentially 0%) and the yield of carbon dioxide is virtually quantitative (approximately 100%) – in this period, digestion occurred as aerobic fermentation to carbon dioxide. The yields of methane and carbon dioxide gases were approximately equal after 250 hours, and after 500 hours, the digestion reached the stationary phase. The methane content of the biogas was in the range of 73 to 79% for the runs, the remainder being principally carbon dioxide. During a 720-hour digestion period, approximately 80 to 85% v/v of the biogas was produced in the first 360 to 430 hours which is an indication that the digester retention time can be designed to a shorter period (360 to 430 hours) instead of the longer period (720 hours).

The final stage in the process is the disposal of the any waste. Essentially all the water entering the system will be present in the effluent. Direct recycle of the water after separation from the sludge cannot be practiced, as this will result in a buildup of toxic substances and eventual failure of the system. It is possible that some fraction of the water may be safely recycled, although data on this aspect have not been seen. Treatment of this large volume of water to remove the toxic constituents is costly and is likely to be uneconomical other than in large-scale operations.

Typically, it can be assumed that the water, which is considered to have some nutritional value, can be used for irrigation of growing crops. However, serious consideration must be given to the effect of trace metals and other toxic materials present in the water and the effects of these constituents on the crops. In addition, subject to the presence of non-toxic constituents (or the lack of toxic constituents) in the sludge, it also may be used for land application and will generally have higher nitrogen content than the original material. On an absolute (feedstock-to-sludge) basis, there may be less nitrogen retention due to losses of the nitrogen as ammonia (NH_3), and there may be additional losses on land application since the nitrogen in the sludge is in a more volatile form than the nitrogen in the original feedstock. Nevertheless, the sludge resulting from the digestion of animal manure is generally considered (subject to a critical analysis of the constituents of the sludge) to have improved fertilizer value over the original feedstock. During digestion, the volatile fatty acid concentration is lower and the pH higher. Nearly all digester plants have ancillary processes to treat and manage all of the by-products. Before storage and use, the gas stream is dried and sweetened by removal of sulfur compounds. The sludge liquor mixture has to be separated by one of a variety of ways, the most common of which is filtration. Excess water is also sometimes treated in sequencing batch reactors (SBR) for discharge into irrigation systems.

Essentially all organic material can be digested except for the stable woody materials since the anaerobic microorganisms are unable to degrade lignin. The biogas which is formed has a high calorific value (heat content) and is considered as a renewable energy source. The main disadvantages of this process are (i) the possible presence of volatile siloxanes in the biogas that can cause serious damage in the energy users' engine and boiler due to the formation of microcrystalline silica; and (ii) the increased concentration of heavy metals and various industrial organic chemicals in the residual sludge due to the significant reduction of the organic fraction during digestion, leaving the mineral and non-degradable fraction untouched.

Anaerobic digestion produces a clean and environmentally friendly fuel, although it contains carbon dioxide, water vapor, hydrogen, hydrogen sulfide, and siloxane derivatives (i.e., compounds having a molecular structure

based on a chain of alternate silicon and oxygen atoms, -O-Si-O-Si-, especially – as in silicone derivatives – with organic groups attached to the silicon atoms).

As a note of caution, a mixture of biogas (predominantly methane) and air can be explosive. Methane in concentrations of between 5% and 15% v/v in air is explosive, and air should not be allowed to enter the digester or gasholder. All piping and equipment must be sealed properly to prevent gas from escaping to the outside. In addition, all electrical installations must be of the explosion-proof type, as the smallest spark could ignite escaped gases.

Biomass feedstocks generally produce a biogas rich in methane. This medium-to-high Btu (heat content) gas can, in some instances, be upgraded to a substitute natural gas (SNG). However, depending on the feedstock, non-negligible amounts of sulfur are also produced (Table B-13).

Table B-13 Comparison of different biogas feedstocks.

Feedstock	Sulfur content*	Product sulfur*
Liquid and solid manure	300-500	0.5
Organic waste	100-300	0.3
Wood chips	300-1000	0.3
Sewage sludge	300-500	0.6

Biological Hydrogen Production

Biological hydrogen (biohydrogen) is hydrogen produced biologically. The main reactions involve fermentation of sugar derivatives, such as glucose:

A related reaction produces formic acid (leading to the potential for the production of formate derivatives (esters of formic acid) instead of carbon dioxide:

See also: Biohydrogen.

Biomass

Biomass refers to biological material derived from living or recently living organisms, such as plants or plant-derived materials. As an energy source, biomass can either be used directly via combustion to produce heat, or indirectly after converting it to various forms of biofuel. Conversion of biomass to biofuel can be achieved by different methods, which are broadly classified into: (i) thermal, (ii) chemical, and (iii) biochemical methods. This biomass conversion can result in fuel in gas, liquid, or solid form.

Biomass is a renewable energy source unlike other resources such as crude oil, natural gas, tar sand, coal, and oil shale. Agricultural products specifically grown for biofuel production include crops such as corn, soybeans, rapeseed, wheat, sugar beet, sugar cane, palm oil, *Jatropha*, as well as wood (Table B-14).

Biomass is generally produced in a sustainable manner from water and carbon dioxide by photosynthesis. There are three main categories of biomass—primary, secondary, and tertiary.

Table B-14 Major categories of biomass feedstocks.

Algae	Prokaryotic algae, Eukaryotic algae, Kelps
Aquatic plants	Algae, Water weed, Water hyacinth, Reed and rushes
Biorenewable wastes	Agricultural wastes, Crop residues, Mill wood wastes, Urban wood wastes, Urban organic wastes
Energy crops	Short rotation woody crops, Herbaceous woody crops, Grasses, Starch crops, Sugar crops, Forage crops, Oilseed crops, Switchgrass, Miscanthus
Food crops	Grains, Oil crops
Forest products	Wood; Logging residues; Trees, shrubs, and wood residues; Sawdust, bark etc.
Landfill	Hazardous waste, Non-hazardous waste, Inert waste, Liquid waste
Lichens	Crustose lichens, Foliose lichens, Fruticose lichen
Mosses	Bryophyta, Polytrichales
Organic waste	Municipal solid waste, Industrial organic wastes, Municipal sewage, and sludge

Biomass is biological organic matter but is more often used to refer to (i) energy crops grown specifically to be used as fuel, such as fast-growing trees or switch grass, (ii) agricultural residues and by-products, such as straw, sugarcane fiber, and rice hulls, and (iii) residues from forestry, construction, and other wood-processing industries.

Many different types of biomass can be grown for the express purpose of energy production (Table B-15).

Table B-15 Sources, processing options, and uses of biomass-derived products*.

Resources	Collection	Conversion	End products
Stage 1	Stage 2	Stage 3	Stage 4
Agricultural crops			
Energy crops			
Forestry			
Herbaceous plants			
Oil-bearing plants			
Wastes			
	Harvesting		
	Handling		
		Pretreatment	
		Biochemical processes	
		Chemical processes	
		Physical processes	
		Thermochemical	
			Biodiesel
			Electrical power
			Heat
			Solid fuels
			Transportation fuels

*The sub-categories are listed alphabetically and are not listed in an order of preference for processing. The choice of processing preference is dependent upon the type of biomass and the desired product.

Crops that have been used for energy include sugar cane, corn, sugar beets, grains, elephant grass, kelp (seaweed), and many others. There are two main factors which determine whether a crop is suitable for energy use. Good energy crops have a high yield of dry material per unit of land (dry tonnes/hectare). A high yield reduces land requirements and lowers the cost of producing energy from biomass. Similarly, the amount of energy which can be produced from a biomass crop must be less than the amount of energy required to grow the crop. In some circumstances like the heavily mechanized corn farms in the U.S. Midwest, the amount of ethanol which can be recovered from the corn is barely larger than the fuel required for tractors, fertilizers, and processing.

The components of biomass include triglycerides, sterols, alkaloids, resins, terpenes, terpenoids, and waxes. This includes everything from primary sources of crops and residues harvested/collected directly from the land to secondary sources such as sawmill residuals, to tertiary sources of post-consumer residuals that often end up in landfills. A fourth source, although not usually categorized as such, includes the gases that result from anaerobic digestion of animal manures or organic materials in landfills.

Primary biomass is produced directly by photosynthesis and includes all terrestrial plants now used for food, feed, fiber, and fuel wood. All plants in natural and conservation areas (as well as algae and other aquatic plants growing in ponds, lakes, oceans, or artificial ponds and bioreactors) are also considered primary biomass. However, only a small portion of the primary biomass produced will ever be harvested as feedstock material for the production of bioenergy and by-products.

Biomass feedstocks and fuels exhibit a wide range of physical and chemical properties (Table B-16).

Table B-16 Selected properties of representative biomass materials.

Mass %, dry	Wood	Grain*	Municipal Solid Waste**	Animal Wastes (Manure)
Carbon	50-53	45.0	47.6	35.1
Hydrogen	5.8-7.0	5.8	6.0	5.3
Nitrogen	0-0.3	2.4	1.2	2.5
Sulfur	0-0.1	0	0.3	0.4
Oxygen	38-44	42.5	32.9	38.7
Volatile matter	77-87	70-80	77	76.5
Fixed carbon	13-21	—	11	0
Ash	0.1-2.0	4.0	12	23.5
H/C atom ratio	1.4-1.6	1.5	1.5	1.8
GCV, MJ/kg (dry)	19.8-21.0	16.8	19	13.4
Moisture, %	25-60	16	20	7-35

* Red corn cob (corn stover) contains approximately 25% cellulose, 10% lignin, and 15% moisture.

** Combustible portion; may contain 9% metals and 12% glass/ceramics on an as-received basis.

For example, there are many types of coal and the gross heating value of these types varies from 8,600-12,900 Btu/lb. However, nearly all kinds of biomass feedstocks destined for combustion range from 6,450 to 8,200 Btu/lb. For most agricultural residues, the heating values are even more uniform – approximately 6,450 to 7,300 Btu/lb; the values for most woody materials are 7,750 to 8,200 Btu/lb. Moisture content is probably the most important determinant of heating value. Air-dried biomass typically has approximately 15 to 20% moisture, whereas the moisture content for oven-dried biomass is around 0%. Moisture content is also an important characteristic of coals, varying in the range of 2 to 30%. However, the bulk density (and hence energy density) of most biomass feedstocks is generally low, even after densification, approximately 10 and 40% of the bulk density of most fossil fuels. Liquid biofuels have comparable bulk densities to fossil fuels.

Combustion offers the most direct route for energy recovery from biomass, and is an effective means of utilizing the total energy content of whole wood and other biomass. Technology for small-scale combustion is certainly well

developed. Larger-scale operation for electricity generation at the 5 to 50 MW level should be feasible, although it is not expected to be economically competitive with crude oil- or natural-gas-fired systems. Due to the large land area over which wood must be harvested, the seasonal nature of the supply, and the large volume of material to be transported and stored, the reliable provision of wood to a large plant can present considerable problems.

Biofuels are derived from biomass and have the potential to produce fuels that are more environmentally benign than crude oil-based fuels. In addition, ethanol, a crop-based fuel alcohol, adds oxygen to gasoline thereby helping to improve vehicle performance and reduce air pollution. Biodiesel, an alternative or additive to crude oil diesel, is a nontoxic, renewable resource created from soybean or other oil crops.

Direct biofuels are biofuels that can be used in existing unmodified crude oil engines. Because engine technology changes all the time, direct biofuel can be hard to define; a fuel that works well in one unmodified engine may not work in another. In general, newer engines are more sensitive to fuel than older engines, but new engines are also likely to be designed with some amount of biofuel in mind.

See also: Biofuels.

Biomass Ash

The mineral matter in biomass is reflected in the yield of mineral ash that is produced during combustion of the biomass. Biomass ash is naturally alkaline. The mineral matter content of wood is small wood but can be as high as 20% w/w for some types of biomass. The alkali nature of ash tends to lower the fusion point of the ash thereby leading to fouling and slagging. An increase in the ash content can also arise from the presence of non-indigenous contaminants such as soil, rocks, plastic, metals, and various chemical treatments of the biomass. Those contaminants can lead to severe problems like pollutant formation, fouling, and slagging.

Biomass with high content of alkali (and chlorine) has often caused problems with the formation of deposits and corrosion. Using additives rich in silicon, aluminum, calcium, potassium, sulfur, or calcium can reduce these problems.

Slagging in combustion units is caused by molten ash and is one of the main drawbacks with using biomass fuels, especially when waste biomass fuels originating from industry or agricultural production are used. The problems are caused by the typically higher content of mineral matter in these fuels but also due to the typically lower ash melting temperatures compared to fossil fuels or pure wood.

The key technical ash-related problems encountered by operators of biomass combustors and boilers have been associated with (i) the formation of fused or partly fused agglomerates and slag deposits at high temperatures within furnaces and stoves, (ii) the formation of bonded ash deposits and accumulations of ash materials at lower temperatures on surfaces in the convective sections of boilers, (iii) the accelerated metal wastage of furnace and boiler components due to gas-side corrosion under ash deposits, and due to ash-particle impact erosion or ash abrasion of boiler components and other equipment, (iv) the formation and emission of sub-micron aerosols and fumes, (v) the effect of biomass ash on the performance of flue gas cleaning equipment, and (vi) the handling, utilization, and disposal of ash residues from biomass combustion plants and mixed ash residues from the co-firing of biomass in coal-fired boilers.

Currently, there are solutions for combusting fuels with lower ash melting temperatures, such as wheat straw, but they have to be adapted specifically to a specific quality of the fuel. Fuel quality, however, varies widely between different types of biomass and biomass waste and can also vary with the season and especially during the handling of the fuel, which can cause contamination with soil, dirt, or other waste materials.

For biomass gasification and pyrolysis systems, the ash-related issues are largely similar to those for combustion, i.e., the accumulation of ash material within the reactor and associated equipment, the effect of ash on the integrity of the process plant and heat exchangers and the ash-related environmental effects of the process.

See also: Ash.

Biomass Chemistry

Biomass is typically composed of 75 to 90% by weight sugar species, the other 10 to 25 wt% being mainly lignin. The energy in biomass is the chemical energy associated with the carbon and hydrogen atoms contained in oxidizable

organic compounds which are the source of the carbon and hydrogen is carbon dioxide and water. The conversion by plants of carbon dioxide and water to a combustible organic form occurs by the process of photosynthesis in which solar energy and chlorophyll are the important players.

Chlorophyll, present in the cells of green plants, absorbs solar energy and makes it available for the photosynthesis, which may be represented by the simplified chemical reaction:

The oxidizable organic materials that are produced by photosynthesis and which determine the properties of the plant matter of relevance to biomass energy utilization are carbohydrates and lignin.

All of the carbohydrates present are saccharides (i.e., sugars) or polymers of sugars (i.e., polysaccharides) that fall into three types: (i) starch, (ii) cellulose, and (iii) hemicellulose. The simple sugars include glucose, fructose, and the like, while the polymeric sugars such as cellulose and starch can be readily broken down to their constituent monomers by hydrolysis, preparatory to conversion to ethanol or other chemicals.

Starch is a granular polysaccharide which accumulates in the storage tissues of plants such as seeds, tubers, roots, and stem pith. It is an important constituent of corn, potato, rice, and tapioca. Starch consists of 10 to 20% amylose, which is water soluble, and 80 to 90% amylopectin, which is insoluble. Both the constituents of starch are polymers of glucose, with amylose linked in chain structures, while amylopectin is a highly branched structure. Starch is not as chemically resistant as cellulose, and can be readily hydrolyzed by dilute acids and enzymes to fermentable sugars.

Hemicelluloses are polysaccharides that occur in association with cellulose. They are chemically different from cellulose, are amorphous, and have much lower molecular weight mass. While cellulose is built from the single sugar glucose, most hemicelluloses contain two to four different sugars as building blocks. Glucose is a component of some hemicelluloses, although xylose is a dominant sugar in hardwood hemicellulose, and mannose is important in softwood hemicellulose. Unlike the other sugars described so far, xylose contains only 5 carbon atoms and is a pentose.

The fraction of the cellulose containing xylose polymers is often referred to as pentosan. Hemicellulose is more soluble than cellulose, is dissolved by dilute alkaline solutions, and can be relatively readily hydrolyzed to fermentable sugars.

In contrast, lignin is a complex structure containing aromatic groups and is less readily degraded. Although lignocellulose is one of the cheapest and most abundant forms of biomass, it is difficult to convert this relatively unreactive material into sugars. Among other factors, the walls of lignocellulose are composed of lignin, which must be broken down in order to render the cellulose and hemicellulose accessible to acid hydrolysis. For this reason, many programs focused on ethanol production from biomass are based almost entirely on the fermentation of sugars derived from the starch in corn grain.

Lignin is the final major constituent of plant material important to biomass processing, and it is a complex chemical compound that is most commonly derived from wood and is an integral part of the cell walls of plants. The chemical structure of lignin is unknown and, at best, can only be represented by a hypothetical formula, the veracity of which is questionable. In fact, lignin is one of most abundant organic compounds on earth after cellulose and chitin.

By way of clarification, chitin ($\text{C}_8\text{H}_{13}\text{O}_5\text{N})_n$ is a long-chain polymeric polysaccharide of β -glucose that forms a hard, semitransparent material found throughout the natural world. Chitin is the main component of the cell walls of fungi and is also a major component of the exoskeletons of arthropods, such as the crustaceans (e.g., crab, lobster, and shrimp), and the insects (e.g., ants, beetles, and butterflies), and of the beaks of cephalopods (e.g., squids and octopuses).

Like hemicellulose, lignin is amorphous and more soluble than cellulose. It may be removed from wood by steaming or by dissolving in hot aqueous or aqueous bisulfite solution. Lignin resists hydrolysis and is resistant to microbial degradation.

Lignin fills the spaces in the cell wall between cellulose, hemicellulose, and pectin components and is covalently linked to hemicellulose. Lignin also forms covalent bonds to polysaccharides and thereby cross-links different plant polysaccharides. It confers mechanical strength to the cell wall (stabilizing the mature cell wall) and therefore the entire plant.

See also: Hemicellulose, Lignin, Starch.

Biomass Combustion

Combustion is widely used on various scales to convert biomass energy to heat and/or electricity with the help of a steam cycle (stoves, boilers, power plants). Production of heat, power, and (process) steam by means of combustion is applied for a wide variety of fuels, and from small scale (for domestic heating) to a scale in the range of 100 MWe. Co-combustion of biomass in (large and efficient) coal-fired power plants is an especially attractive option as well because of the high conversion efficiency of these plants. It is a proven technology, although further improvements in performance are still possible.

Net electrical efficiencies for biomass combustion power plants range from 20 to 40%. The higher efficiencies are obtained with systems over 100 MW_e or when the biomass is co-combusted in coal-fired power plants.

See also: Biomass – Direct Combustion.

Biomass Composition and Properties

Biomass is a term used to describe any material of recent biological origin, including plant materials such as trees, grasses, agricultural crops, and even animal manure. The bulk composition (in terms of the amounts of cellulose, hemicellulose, and lignin) is, as might be expected variable opening upon the source and types of the biomass (Table B-17).

Table B-17 Bulk composition of different biomass type (% w/w, dry basis).

Biomass type	Cellulose	Hemicellulose	Lignin
Peat	10	32	44
Rice husks	30	25	12
Straw (wheat)	40	28	17
Wood (bark)	34	16	34
Wood (hard)	39	35	20
Wood (soft)	41	24	28

The elemental composition also shows some variation with the source of the biomass (Table B-18).

Table B-18 Elemental composition, ash production, and heat content of biomass types*.

Biomass, % w/w**	C	H	N	O	Ash
Miscanthus	49.5	6.2	0.6	43.7	3.3
Peat	53.1	5.5	1.3	38.1	5.6
Reed grass	49.4	6.3	1.6	42.7	8.8
Straw (wheat)	49.6	6.2	0.6	43.6	4.7
Sugar cane	49.5	6.2	0.5	43.8	3.7
Wood (bark)	47.2	5.6	0.3	46.9	3.9
Wood (birch)	48.8	6.0	0.5	44.2	0.5
Wood (pine)	49.3	6.0	0.5	44.2	0.5

*Listed alphabetical rather than by any preference.

**Dry basis

The obvious data are those relating to the amount of oxygen in the biomass which will require (at some stage of the refining) a hydrodeoxygenation step.

In terms of the bulk composition, other biomass components, which are generally present in minor amounts, include (i) triglyceride derivatives, which are ester derivatives of glycerol three fatty acids, (ii) sterol derivatives, which are also known as steroid alcohol derivatives), (iii) alkaloid derivatives, which form a class of naturally occurring organic compounds that mostly contain basic nitrogen atoms, (iv) terpene derivatives, which are the primary constituents of the essential oils of many types of plants and flowers, (v) terpenoid derivatives, which are sometimes referred to as isoprenoids and form a large and diverse class of naturally occurring organic chemicals derived from terpenes – most are multicyclic structures with oxygen-containing functional groups), and (vi) wax derivatives, which are a diverse class of organic compounds that are lipophilic, malleable solids near ambient temperatures and include higher molecular weight alkane derivatives and lipids, typically with melting points above approximately 40°C (104°F) and melt to give low-viscosity liquids. Waxes are insoluble in water but soluble in organic, nonpolar solvents. Natural waxes of different types are produced by plants and animals and occur in crude oil).

This list (above) includes everything from primary sources of crops and residues harvested/collected directly from the land, to secondary sources such as sawmill residuals, to tertiary sources of post-consumer residuals that often end up in landfills. A fourth source, although not usually categorized as such, includes the gases that result from anaerobic digestion of animal manures or organic materials in landfills (Wright et al., 2006).

Thus, knowledge of the composition of a biomass feedstocks is critical to the selection of the varieties with optimized properties for downstream conversion (De Jong, 2014). This can be partially achieved by selecting varieties with biomass composition that are better suited to the conversion process. Lignocellulosic biomass displays considerable recalcitrance to biochemical conversion because of the inaccessibility of its polymer components to enzymatic digestion and the release or production of fermentation inhibitors during pretreatment. If the ratio of hemicellulose, cellulose, and lignin in a woody biomass feedstock was optimized for the specific biochemical conversion method, then the pretreatment methods could be reduced or avoided.

Plants use the light energy from the sun to convert water and carbon dioxide to sugar derivatives (photosynthesis) that can be stored within the plant system. Some plants, such as sugar cane and sugar beets, store energy as simple sugars, while other plants store the energy as more complex starch derivative. These plants include grains like corn which are prominent food sources. Another type of plant matter – cellulosic biomass – is composed of complex sugar polymers, and is not generally used as a food source. Cellulosic feedstocks under consideration for biofuels include (i) agricultural residues which is the leftover material from crops, such as the stalks, leaves, and husks of corn plants, (ii) forestry wastes, which include chips and sawdust from lumber mills, dead trees, and tree branches, (iii) municipal solid waste, which includes household garbage and paper products, (iv) food processing and other industrial wastes such as black liquor, which is a paper manufacturing by-product (Table B-19), and (v) energy crops, such as fast-growing trees and grasses) developed just for this purpose.

Table B-19 Composition of black liquor.

Element	% w/w
Carbon	35.7
Hydrogen	3.7
Nitrogen	≥0.1
Oxygen	35.8
Sulfur	4.4
Chlorine	0.3
Potassium	1.1
Sodium	19.0

The main components of these types of biomass are (i) cellulose which is the most common form of carbon in biomass, accounting for 40 to 60% w/w of the biomass, depending on the biomass source and which is a complex sugar polymer, or polysaccharide, made from the six-carbon sugar, glucose – the crystalline structure of cellulose

renders it resistant to hydrolysis, the chemical reaction that releases simple, fermentable sugars from a polysaccharide; (ii) hemicellulose which is also a major source of carbon in biomass, at levels of between 20% and 40% w/w of the biomass and is a complex polysaccharide made from a variety of five-carbon and six-carbon sugar derivative – it is relatively easy to hydrolyze into simple sugars, but the sugars can be difficult to ferment, and (iii) lignin which is a complex polymer that makes up 10% to 24% w/w of the biomass and provides structural integrity in plants – it remains as residual material after the sugars in the biomass have been converted.

In the simplest sense, biomass is carbon based and is composed of a mixture of organic molecules containing hydrogen, usually including atoms of oxygen, often nitrogen and also small quantities of other atoms, including alkali, alkaline earth, and heavy metals. However, because of the wide variations in the character and properties of biomass, it is anticipated and realized that the character and properties of the biofuels produced from biomass are very dependent upon the initial biomass. The exception is the fuels produced by gasification and Fischer-Tropsch synthesis.

In addition to the chemical composition, three properties of biomass that are significant to the performance of biomass as a fuel are (i) mineral matter content, manifested in thermal processes as mineral ash, (ii) susceptibility of the mineral matter to slagging and fouling, and (iii) the volatile matter content. The mineral matter content is the mass fraction of biomass composed of non-combustible inorganic material. Grasses, bark, and field crop residues typically have much higher content of mineral matter than wood. Systems that are designed to combust wood can be overwhelmed by the volume of ash if other biofuels are used. Slagging and fouling are problems that occur if ash begins to melt during combustion, forming deposits on combustor surfaces (fouling) or leaving hard chunks of glassy material in the bottom of the combustion chamber (slag, often referred to as clinkers).

Certain mineral components in biomass fuels, primarily silica, potassium, and chlorine, can cause these problems to occur at lower temperatures than normal. Dirt contamination also adds to the mineral content and associated slagging and fouling problems, so it is important that biomass feedstock be as clean (dirt-free) as possible. Slagging and fouling is minimized by keeping combustion temperatures low. Alternately, some biomass combustion equipment is designed to encourage the formation of clinkers (often referred to in the singular form, clinker) but is able to dispose of the hardened ash in an effective manner.

The content of volatile constituents (or volatile matter) in a fuel is a lesser-known property that refers to the fraction of the fuel that will readily volatilize (turn to gas) when heated to a high temperature. Fuels with high volatiles content will tend to vaporize before combusting, whereas fuels with low volatiles will burn primarily char. This affects the performance of the combustion chamber and should be taken into account when designing a combustor.

Other properties such as the particle size and density of biomass fuels are also important as they affect the thermal processing characteristics (especially the combustion characteristics) of biomass, especially the rate of heating and drying during the thermal process. The feedstock particle size also dictates the type of handling equipment required. For example, the incorrect size fuel will negatively impact process efficiency and may cause jamming or damage to the handling equipment. Smaller-sized fuel is more common for commercial-scale systems because smaller fuel is easier to use in automatic feed systems and allows for finer control of the processing rate by controlling the rate at which fuel is added to the reaction chamber. Fuel particle size and density are probably the most overlooked factors affecting fuel performance and should be given careful consideration when selecting a fuel type. Bulk density is the mass of a material divided by the volume it occupies. Bulk density of granular materials is dependent on the manner in which it is handled insofar as freely settled material has a lower bulk density than tapped or compacted materials.

Biomass – Conversion Technologies

There are many bioenergy routes which can be used to convert raw biomass feedstock into a final energy product. Several conversion technologies have been developed that are adapted to the different physical nature and chemical composition of the feedstock, and to the energy service required (heat, power, transport fuel). Upgrading technologies for biomass feedstocks (e.g., pelletization, torrefaction, and pyrolysis) are being developed to convert bulky raw biomass into denser and more practical energy carriers for more efficient transport, storage, and convenient use in subsequent conversion processes.

The production of heat by the direct combustion of biomass is the leading bioenergy application throughout the world and is often cost-competitive with fossil fuel alternatives. Technologies range from rudimentary stoves to sophisticated modern appliances. For a more energy-efficient use of the biomass resource, modern, large-scale heat applications are often combined with electricity production in combined heat and power (CHP) systems.

Different technologies exist or are being developed to produce electricity from biomass. Co-combustion (also called co-firing) in coal-based power plants is the most cost-effective use of biomass for power generation. Dedicated biomass combustion plants, including MSW combustion plants, are also in successful commercial operation, and many are industrial or district heating CHP facilities. For sludges, liquids, and wet organic materials, anaerobic digestion is currently the best-suited option for producing electricity and/or heat from biomass, although its economic case relies heavily on the availability of low-cost feedstock. All these technologies are well established and commercially available.

There are few examples of commercial gasification plants, and the deployment of this technology is affected by its complexity and cost. In the longer term, if reliable and cost-effective operation can be more widely demonstrated, gasification promises greater efficiency, better economics at both small- and large-scale and lower emissions compared with other biomass-based power generation options. Other technologies (such as Organic Rankine Cycle and Stirling engines) are currently in the demonstration stage and could prove economically viable in a range of small-scale applications, especially for CHP.

In the transport sector, first-generation biofuels are widely deployed in several countries – mainly bioethanol from starch and sugar crops and biodiesel from oil crops and residual oils and fats. Production costs of current biofuels vary significantly depending on the feedstock used (and their volatile prices), and on the scale of the plant. The potential for further deploying these first-generation technologies is high, subject to sustainable land use criteria being met.

First-generation biofuels face both social and environmental challenges, largely because they use food crops which could lead to food price increases and possibly indirect land use change. While such risks can be mitigated by regulation and sustainability assurance and certification, technology development is also advancing for next-generation processes that rely on non-food biomass (e.g., lignocellulosic feedstocks such as organic wastes, forestry residues, high-yielding woody or grass energy crops, and algae). The use of these feedstocks for second-generation biofuel production would significantly decrease the potential pressure on land use, improve greenhouse gas emission reductions when compared to some first-generation biofuels, and result in lower environmental and social risk.

Second-generation technologies, mainly using lignocellulosic feedstocks for the production of ethanol, synthetic diesel, and aviation fuels, are still immature and need further development and investment to demonstrate reliable operation at commercial scale and to achieve cost reductions through scale-up and replication. The current level of activity in the area indicates that these routes are likely to become commercial over the next decade. Future generations of biofuels, such as oils produced from algae, are at the applied R&D stage, and require considerable development before they can become competitive contributors to the energy markets.

Further development of bioenergy technologies is needed mainly to improve the efficiency, reliability, and sustainability of bioenergy chains. In the heat sector, improvement would lead to cleaner, more reliable systems linked to higher quality fuel supplies. In the electricity sector, the development of smaller and more cost-effective electricity or CHP systems could better match local resource availability. In the transport sector, improvements could lead to higher quality and more sustainable biofuels.

Ultimately, bioenergy production may increasingly occur in biorefineries where transport biofuels, power, heat, chemicals, and other marketable products could all be co-produced from a mix of biomass feedstocks. The link between producing energy and other materials deserves further attention technically and commercially.

Biomass-Derived Carbon

Biomass plays a unique role in the dynamics of carbon flow in the biosphere. Carbon is biologically cycled when plants such as soybean crops convert atmospheric carbon dioxide to carbon-based compounds through photosynthesis. This carbon is eventually returned to the atmosphere as organisms consume the biological carbon compounds and respire. Biomass-derived fuels reduce the net atmospheric carbon in two ways.

First, they participate in the relatively rapid biological cycling of carbon to the atmosphere (via engine tailpipe emissions) and from the atmosphere (via photosynthesis). Second, they displace fossil fuels. Fossil fuel combustion releases carbon that took millions of years to be removed from the atmosphere; combustion of biomass fuels participates in a process that allows carbon dioxide to be rapidly recycled to fuel. The net effect of shifting from fossil fuels to biomass-derived fuels is thus to reduce the amount of carbon dioxide in the atmosphere.

Because of the differences in the dynamics of fossil carbon flow and biomass carbon flow to and from the atmosphere, biomass carbon is often accounted for separately from carbon derived from fossil fuels.

See also: Biomass, Biomass – Pyrolysis.

Biomass – Direct Combustion

Direct combustion of biomass is a thermochemical technique in which the biomass is burned (combusted) in open air or in the presence of excess air. In this process, the photosynthetically stored chemical energy of the biomass will be converted into gases, unless char is also produced.

There are five thermal approaches that are commonly used to convert biomass into a renewable fuel: direct combustion, gasification, liquefaction, pyrolysis, and partial oxidation.

When biomass is heated under oxygen-deficient conditions, it generates synthesis gas that consists primarily of hydrogen and carbon monoxide. This syngas can be directly burned or further processed for other gaseous or liquid products. In this sense, thermal or chemical conversion of biomass is similar to that of coal.

Indoor direct combustion of biomass fuels in unvented cooking and heating spaces has caused considerable health problems to the direct users, primarily the women and children of developing countries. Biomass fuels, when used improperly in this manner, release considerable amounts of toxic or hazardous gases into the unvented area. These gases are typically: carbon monoxide (CO), nitrogen oxides (NO_x), hydrocarbon derivatives, organics, aldehydes, and trace amounts of aromatics and ketones. As the moisture content of the wood increases, and as other biomass fuels of lower energy content (such as animal and crop waste) are used, the emissions increase.

When the direct combustion of biomass is conducted in a well-ventilated area, biomass burning used for domestic stoves and boilers can be a sound substitute for combustion of conventional fossil fuel.

Most electrical power generation systems are relatively inefficient, due to the loss of a significant portion of energy, as much as half to two-thirds, in a form of waste heat. If this heat is used efficiently for industrial manufacture, space heating, district heating, or other purposes, the overall efficiency can be greatly enhanced. Therefore, smaller bio-power systems are more suitable for cogeneration type of processes than much larger counterparts.

Biomass – Drying

Biomass with a high moisture content such as sludge is often used as fuel in power plant without proper drying which reduces the efficiency of the boiler. However, by use of a drying process, moisture can be largely removed from biomass. The result is a reduction in the weight of the biomass. This leads to a reduction of the processing costs, as well as of the costs for storage and transport. The dried end product is frequently used as a plant nutrient or it can be used as a fuel. This, however, depends on the properties of the biomass that needs to be dried.

Using dry fuel in a direct combustion boiler results in (i) improved efficiency, (ii) increased steam production, (iii) reduced ancillary power requirements, (iv) reduced fuel use, (v) lower emissions, and (vi) improved boiler operation. One of the main reasons for these benefits is an increased flame temperature. With wet fuel, some heat of combustion is used to evaporate the water in the fuel. With dry fuel, all the heat of combustion goes into heating the air and products of combustion. As a result, dry fuels have a flame temperature on the order of 1,260 to 1,370°C (2,300 to 2,500°F), while green wood has a combustion temperature of approximately 980°C (1,800°F). In cold climates, the heat of fusion of any ice that may be mixed with the fuel will also have a significant effect on the flame temperature.

Dryers can be broadly divided into two categories based on how heat is provided for drying. In direct dryers, the material gets heat from direct contact with a fluid providing the heat – either hot air or hot steam. With indirect drying, the material being dried is separated from the heat source by a heat exchange surface.

Directly heated dryers can be further divided into two more categories: air and superheated steam dryers (SSDs). In air dryers, hot air is contacted with the material to be dried. The air loses its sensible heat and provides the latent heat of evaporation to dry the material. The air also removes the water vapor that is evaporated. The material can be agitated by some mechanical means or by the flowing air.

In superheated steam dryers, the heating fluid is steam rather than air, but the concept is the same. The superheated steam is contacted with the biomass material and loses some of its sensible heat to provide the latent heat of evaporation to dry the fuel. The steam, however, remains above its saturation temperature, so it doesn't condense. The water vapor leaving the biomass is heated by the superheated steam, so the net result is a larger amount of steam at a lower temperature than when the steam entered the dryer. The excess steam is removed, and the remainder is reheated and recycled back to the dryer.

In the case of the indirectly heated dryer operated under a vacuum, or with a superheated steam dryer, the latent heat of evaporation of the water vapor is easy to recover because it is not diluted by air. With vacuum drying, this heat is available only at a low temperature, but with superheated steam drying, the dryer can be designed to produce steam at practically any pressure for use in other parts of the plant.

There are several steps to drying. First, the material must be heated from the temperature at which it entered the dryer, up to the wet bulb temperature, to produce a driving force for water to leave the wet material. Next, any surface moisture on the material is evaporated – this occurs fairly quickly. Once all the surface moisture is removed, the material must be heated to drive water from the inside of the biomass to the surface so it can evaporate. This occurs during the “falling rate period” when the rate of drying drops as the material becomes drier. During the falling rate period, the surface temperature of the material remains close to the wet bulb temperature. Once the material is completely dry, it begins to heat up to the surrounding temperature, because water is no longer present to keep the temperature low.

Rotary Dryers

Rotary dryers are the most common type for biomass. There are several variations of rotary dryers, but the most widely used is the directly heated single-pass rotary dryer. In this type of dryer, hot gases are contacted with biomass material inside a rotating drum. The rotation of the drum, with the aid of flights, lifts the solids in the dryer so they tumble through the hot gas, promoting better heat and mass transfer. If contamination is not a concern, hot flue gas can be fed directly into the dryer. Other options include using a burner or a steam heater to raise the temperature of incoming air.

The exhaust gases leaving the dryer may pass through a cyclone, multicyclone, baghouse filter, scrubber, or electrostatic precipitator (ESP) to remove any fine material entrained in the air. An air fan may not be required depending on the dryer configuration. If one is needed, it is usually placed after the emissions control equipment to reduce erosion of the fan, but may also be placed before the first cyclone to provide the pressure drop through downstream equipment.

The inlet gas temperature to rotary biomass dryers can vary from 232 to 1,095°C (450 to 2,000°F). Outlet temperatures from rotary dryers vary from 70 to 110°C (160 to 230°F) with most of the dryers having outlet temperatures higher than 104°C (220°F) to prevent condensation of acids and resins. Retention times in the dryer can be less than a minute for small particles and 10 to 30 minutes for larger material.

Flash Dryers

In a flash or pneumatic dryer, the solids are mixed with a high-velocity hot air stream. The intimate contact of the solids with the air results in very rapid drying. The solids and air are separated using a cyclone, and the gases continue through a scrubber to remove any entrained particulate material.

Gas temperatures are slightly lower for flash dryers than for rotary dryers, but they still operate at temperatures above the combustion point. The solids retention time in a flash dryer is typically less than 30 seconds, minimizing the fire hazard.

Disk Dryers

For smaller flows of material, a disk dryer or “porcupine” dryer (Figure 3) is an option. In a disk dryer, solids are heated by condensing steam inside of a central shaft with many hollow disks that increase the area for heat transfer. Fingers or breaker bars mix the material and act to keep the heat transfer surfaces free of buildup. The disk dryer can be operated under a vacuum or under pressure, and the condensate from inside the heating shaft can be recovered and returned to the boiler.

Cascade Dryers

Cascade or spouted dryers (Figure 4) are commonly used for drying grain, but they can be used for other types of biomass. Material is introduced to a flowing stream of hot air as it enters an enclosed chamber. The material is thrown into the air, then falls, or cascades, back to the bottom to be lifted again. Some of the material is drawn out through openings in the side of the chamber that control the residence time and amount of drying. *Superheated*

Steam Dryers

Most superheated steam dryers are similar to flash dryers, except that the fluid suspending the solids and providing heat is steam instead of air. Under normal operation, the wet material is mixed with enough superheated steam to dry the material and still end up with superheated steam. Typically 90% of the steam leaving the dryer is recirculated while 10% of the steam, representing the amount of water evaporated from the biomass, is removed and either condensed or used directly in other parts of the plant.

See also: Drying.

Biomass Energy

Biomass energy is energy generated or produced by living or once-living organisms. The most common biomass materials used for energy are plants, such as corn and soy, above. The energy from these organisms can be burned to create heat or converted into electricity.

Biomass contains energy first derived from the sun: Plants absorb the sun’s energy through photosynthesis, and convert carbon dioxide and water into nutrients (carbohydrates). The energy from these organisms can be transformed into usable energy through direct and indirect means. Biomass can be burned to create heat (direct), converted into electricity (direct), or processed into biofuel (indirect).

Thermal Conversion

Biomass can be burned by thermal conversion and used for energy. Thermal conversion involves heating the biomass feedstock in order to burn, dehydrate, or stabilize it. The most familiar biomass feedstocks for thermal conversion are raw materials such as municipal solid waste (MSW) and scraps from paper or lumber mills. Different types of energy are created through direct firing, co-firing, pyrolysis, gasification, and anaerobic decomposition.

Before biomass can be burned, however, it must be dried. This chemical process is called torrefaction. During torrefaction, biomass is heated to approximately 200 to 320°C (390 to 610°F). The biomass dries out so completely that it loses the ability to absorb moisture, or rot. It loses approximately 20% of its original mass, but retains 90% of its energy. The lost energy and mass can be used to fuel the torrefaction process.

During torrefaction, biomass becomes a dry, blackened material. It is then compressed into briquettes. Biomass briquettes are very hydrophobic, meaning they repel water. This makes it possible to store them in moist areas. The briquettes have high energy density and are easy to burn during direct or co-firing.

Direct Firing and Co-Firing

Most briquettes are burned directly. The steam produced during the firing process powers a turbine, which turns a generator and produces electricity. This electricity can be used for manufacturing or to heat buildings.

Biomass can also be co-fired, or burned with a fossil fuel. Biomass is most often co-fired in coal plants. Co-firing eliminates the need for new factories for processing biomass. Co-firing also eases the demand for coal. This reduces the amount of carbon dioxide and other greenhouse gases released by burning fossil fuels.

Pyrolysis

Pyrolysis is a related method of heating biomass. During pyrolysis, biomass is heated to 200 to 300°C (390 to 570°F) without the presence of oxygen. This keeps it from combusting and causes the biomass to be chemically altered.

Pyrolysis produces a dark liquid called pyrolysis oil, a synthetic gas called syngas, and a solid residue called biochar. All of these components can be used for energy. Pyrolysis oil, sometimes called bio-oil or biocrude, is a type of tar. It can be combusted to generate electricity and is also used as a component in other fuels and plastics as an alternative to crude oil.

Biochar is a type of charcoal. Biochar is a carbon-rich solid that is particularly useful in agriculture. Biochar enriches soil and prevents it from leaching pesticides and other nutrients into runoff. Biochar is also an excellent carbon sink. Carbon sinks are reservoirs for carbon-containing chemicals, including greenhouse gases.

Gasification

Biomass can also be directly converted to energy through gasification. During the gasification process, a biomass feedstock (usually MSW) is heated to more than 700°C (1,300°F) with a controlled amount of oxygen. The molecules break down, and produce syngas and slag.

Synthesis gas is a combination of hydrogen and carbon monoxide. During gasification, syngas is cleaned of sulfur, particulates, mercury, and other pollutants. The clean syngas can be combusted for heat or electricity, or processed into transportation biofuels, chemicals, and fertilizers. Synthesis gas can also be converted into fuel (such as synthetic natural gas). It can also be converted into methane and used as a replacement for natural gas.

Slag forms as a glassy, molten liquid and can be used to make shingles, cement, or asphalt.

Anaerobic Decomposition

Anaerobic decomposition is the process where microorganisms, usually bacteria, break down material in the absence of oxygen. Anaerobic decomposition is an important process in landfills, where biomass is crushed and compressed, creating an anaerobic (or oxygen-poor) environment.

In an anaerobic environment, biomass decays and produces methane, which is a valuable energy source. This methane can replace fossil fuels. In addition to landfills, anaerobic decomposition can also be implemented on ranches and livestock farms. Manure and other animal waste can be converted to sustainably meet the energy needs of the farm.

See also: Alternate Fuels.

Biomass Energy Systems

Biomass has to be produced either by the cultivation of dedicated crops (such as wood by means of short rotation forestry, perennial grasses), by harvesting forest and other residues (thinnings, straw, etc.), or by collecting biomass waste (such as sludge, organic industrial waste, and organic domestic waste). Next, the biomass has to be harvested or collected, then transported, and if necessary, it may have to be stored and transferred.

Biomass can be converted by means of numerous processes. The actual choice of a process will depend on the type and quantity of available biomass feedstock, the desired energy carrier(s) (end-use), environmental standards, economic conditions, and other factors.

Most biomass energy conversion processes can be divided into (i) thermochemical conversion and (ii) biochemical conversion routes, and (iii) mechanical processes. With respect to thermochemical conversion options, a distinction can be made between combustion, gasification and pyrolysis. Biochemical conversion options can be divided into digestion (production of biogas, a mixture of mainly methane and carbon dioxide) and fermentation (such as the production of ethanol). Extraction is another, mainly mechanical, process for producing an energy carrier from biomass (e.g., rapeseed oil from rapeseed). With regard to the energy carriers produced from biomass, a distinction can be made between the production of heat, electricity, and fuels.

See also: Bioconversion Platform, Thermoconversion Platform.

Biomass – Extraction

Extraction is a mechanical conversion process and two well-established technologies for oil extraction are (i) the simple screw press, which is a device for physically extracting the oil from the plant – this technology is well suited to small-scale production of oil as fuel or as foodstuff in rural areas, and (ii) solvent extraction, a chemical process which requires large, sophisticated equipment – this method is more efficient and extracts a greater percentage of the oil from the plant.

The process can be used to derive rapeseed oil from rapeseed. In this case, the process produces not only oil but also rapeseed cake, which is suitable for fodder. Approximately 3 tons of rapeseed is required per ton of oil.

Rapeseed oil can be esterified to obtain rapeseed methyl ester (RME) or biodiesel. This process is being used commercially on a substantial scale, especially in Europe.

See also: Biomass Extraction, Rapeseed.

Biomass Feedstocks

Consideration of biomass feedstocks for processes must go beyond such a simple representation as the van Krevelen diagram since the composition varies with the nature of the feedstock. For most agricultural residues, the heating values are even more uniform – approximately 6,450 to 7,300 Btu/lb, and the values for most woody materials are 7,750 to 8,200 Btu/lb. The moisture content is extremely important in determining the heating value of biomass as well as its suitability as a process feedstock. Air-dried biomass typically has approximately 15 to 20% moisture. The moisture content is also an important characteristic of coals, varying in the range of 2 to 30%. However, the bulk density (and hence energy density) of most biomass feedstocks is generally low, even after densification, approximately 10 and 40% of the bulk density of most fossil fuels. Liquid biofuels have comparable bulk densities to fossil fuels.

Most biomass materials are easier to gasify than coal because they are more reactive with higher ignition stability. This characteristic also makes them easier to process thermochemically into higher-value fuels such as methanol or hydrogen. Ash content is typically lower than for most coals, and sulfur content is much lower than for many fossil fuels. Unlike coal ash, which may contain toxic metals and other trace contaminants, biomass ash may be used as a soil amendment to help replenish nutrients removed by harvest.

Some biomass feedstocks stand out for their peculiar properties, such as high silicon or alkali metal contents – these may require special precautions for harvesting, processing, and combustion equipment. The mineral content can also vary as a function of soil type and the timing of feedstock harvest. In contrast to their fairly uniform physical properties, biomass fuels are rather heterogeneous with respect to their chemical elemental composition.

Among the liquid biomass fuels, biodiesel (vegetable oil ester) is noteworthy for its similarity to crude oil-derived diesel fuel, apart from its negligible sulfur and ash content. Bioethanol has only approximately 70% the heating value of crude oil distillates such as gasoline, but the sulfur content and the ash content are also low. Both of these liquid fuels have lower vapor pressure and flammability than their crude oil-based competitors – an advantage in some cases (e.g., use in confined spaces such as mines) but a disadvantage in others (e.g., engine starting at cold temperatures).

Plants offer a unique and diverse feedstock for chemicals. Plant biomass can be gasified to produce synthesis gas, a basic chemical feedstock and also a source of hydrogen for a future hydrogen economy. In addition, the specific components of plants such as carbohydrates, vegetable oils, plant fiber, and complex organic molecules known as primary and secondary metabolites can be utilized to produce a range of valuable monomers, chemical intermediates, pharmaceuticals, and materials:

Carbohydrates (starch, cellulose, sugars) are readily obtained from wheat and potato, while cellulose is obtained from wood pulp. The structures of these polysaccharides can be readily manipulated to produce a range of biodegradable polymers with properties similar to those of conventional plastics such as polystyrene foams and polyethylene film. In addition, these polysaccharides can be hydrolyzed, catalytically or enzymatically, to produce sugars, a valuable fermentation feedstock for the production of ethanol, citric acid, lactic acid, and dibasic acids such as succinic acid.

Vegetable oils are obtained from seed oil plants such as palm, sunflower, and soya. The predominant source of vegetable oils in many countries is rapeseed oil. Vegetable oils are a major feedstock for the oleo-chemicals industry (surfactants, dispersants, and personal care products) and are now successfully entering new markets such as diesel fuel, lubricants, polyurethane monomers, functional polymer additives, and solvents.

Plant fibers (lignocellulosic fibers) are extracted from plants such as hemp and flax can replace cotton and polyester fibers in textile materials and glass fibers in insulation products.

See also: Biofuels, Biomass.

Biomass – Fermentation

Fermentation is an anaerobic process that breaks down the glucose within organic materials, and the process is a series of chemical reactions that convert sugars to alcohol or acid. Yeast or bacteria are added to the biomass material, which feed on the sugars to produce ethanol and carbon dioxide. The process is used commercially on a large scale in various countries to produce ethanol from sugar crops (sugar cane, beet) and starch crops (maize, wheat).

The biomass is ground down, and the starch is converted by enzymes to sugars. Yeast then converts the sugars to ethanol. Pure ethanol is produced by distillation which is a relatively energy intensive step. Approximately 450 L of ethanol can be produced per tonne of dry corn. The remaining solids can be used as cattle feed. In the case of sugar cane, the remaining bagasse can also be used as fuel for boilers or gasification processes.

Conversion of lignocellulosic biomass (such as wood and grasses) requires acid or enzymatic hydrolysis before the resulting sugars can be fermented to ethanol. Such hydrolysis techniques are currently at the pre-pilot stage.

See also: Fermentation, Fermentation Chemistry.

Biomass Fuel

Solid biofuels such as wood or dried dung have been used since man learned to control fire. On the other hand, liquid biofuels for industrial applications was used since the early days of the car industry.

Nikolaus August Otto, the inventor of the combustion engine, conceived his invention to run on ethanol, while Rudolf Diesel, the inventor of the diesel engine, conceived it to run on peanut oil. Henry Ford originally had designed the Ford Model T, a car produced between 1903 and 1926, to run completely on ethanol, and the desire to mass produce electric cars did not come to fruition at that time. However, when crude oil began being cheaply extracted from deeper in the soil (thanks to oil reserves discovered in Pennsylvania and Texas), cars began using fuels from oil.

Nevertheless, before World War II, biofuels were seen as providing an alternative to imported oil in countries such as Germany, which sold a blend of gasoline with alcohol fermented from potatoes under the name Reichskraftsprit. In Britain, grain alcohol was blended with gasoline by the Distillers Company Ltd under the name Discol. After the World War II, cheap Middle Eastern oil lessened interest in biofuels. Then, with the oil shocks of 1973 and 1979, there was an increase in interests from governments and academics in biofuels. However, interest decreased with the counter-shock of 1986 that made oil prices cheaper again. However, the variation in the price of crude oil continues and is subject to political pressures from oil-producing countries.

The supply of crude oil, the basic feedstock for refineries and for the petrochemicals industry, is finite, and its dominant position will become unsustainable as supply/demand issues erode its economic advantage over other renewable feedstocks. This situation will be mitigated to some extent by the exploitation of more technically challenging fossil resources and the introduction of new technologies for fuels and chemicals production from natural gas and coal.

However, the use of fossil resources at current rates will have serious and irreversible consequences for the global climate. Consequently, there is a renewed interest in the utilization of plant-based matter as a raw material feedstock for the chemicals industry. Plants accumulate carbon from the atmosphere via photosynthesis, and the widespread utilization of these materials as basic inputs into the generation of power, fuels, and chemicals is a viable route to reduce greenhouse gas emissions.

Thus, the crude oil and petrochemicals industries are coming under increasing pressure not only to compete effectively with global competitors utilizing more advantaged hydrocarbon feedstocks but also to ensure that its processes and products comply with increasingly stringent environmental legislation.

The production of fuels and chemicals from renewable plant-based feedstocks utilizing state-of-the-art conversion technologies presents an opportunity to maintain competitive advantage and contribute to the attainment of national environmental targets. Bioprocessing routes have a number of compelling advantages over conventional petrochemicals production; however, it is only in the last decade that rapid progress in biotechnology has facilitated the commercialization of a number of plant-based chemical processes. It is widely recognized that further significant production of plant-based chemicals will only be economically viable in highly integrated and efficient production complexes producing a diverse range of chemical products. This biorefinery concept is analogous to conventional oil refineries and petrochemical complexes that have evolved over many years to maximize process synergies, energy integration, and feedstock utilization to drive down production costs.

See also: Biofuels, Biomass.

Biomass Fuel – Characteristics

Biomass can be converted to thermal energy, liquid, solid, or gaseous fuels, and other chemical products through a variety of conversion processes. These processes include physical conversion to *densified* fuels (e.g., pellets or cubes), thermal conversion through combustion or pyrolysis, chemical conversion, and microbial conversion or fermentation. The abundance of plant organic constituents and other physical and chemical characteristics vary significantly by plant type and the proportions of plant components such as leaves, stems, bark, and twigs in the feedstock.

The design of a biomass power or ethanol facility requires careful consideration of the effects that feedstock characteristics and composition have on the conversion process. Generating electricity and useful heat energy is most frequently done by direct combustion of biomass in a boiler. Energy content, moisture content, and chemical makeup are among the most important biomass characteristics affecting combustion processes. Biomass gasification yields a combustible gas that can be used to generate electricity. Particle size, energy content, moisture content, and volatiles are among the biomass characteristics affecting gasification.

The technology that is closest to commercialization for converting biomass to ethanol involves extracting complex carbohydrates, primarily cellulose and hemicellulose, from the biomass feedstock and reducing these components to simple sugars (a process called hydrolysis).

Cellulose is a long polymer of glucose, and it serves as a structural component of plant cell walls. It is often found in a composite mixture with hemicellulose and lignin. Hemicellulose is a polymer containing a variety of simple sugars and is more soluble than cellulose. Lignin is a ring-type carbohydrate that acts as cement in plant walls. The lignin portion of biomass is not converted to simple sugars through hydrolysis, but lignin can be burned to generate process heat and electricity.

Extracting the carbohydrates may involve “steam explosion” of the cell walls or dissolving the organic constituents with acids, enzymes, or organic solvents. Sugars resulting from hydrolysis are then converted into ethanol through microbial fermentation. The bulk and biochemical composition of the feedstock largely determine ethanol yield because these traits affect the hydrolysis and fermentation processes.

Biomass – Gasification

Although gasification is old technology with respect to coal-based feedstock, it is a developing technology with respect to biomass, since it was never fully embraced on a larger commercial scale. Biomass materials differ from conventional solids fuels such as coal based on the volatile matter. The volatile matter in the coal is less than 20%,

while it is up to 80% in biomass materials – the constituents of the gas are variable and are dependent upon the process parameters and the feedstock (Table B-20).

Table B-20 Composition of synthesis gas from biomass gasification.

Constituents	% v/v (dry, nitrogen free)
Carbon monoxide (CO)	28-36
Hydrogen (H ₂)	22-32
Carbon dioxide (CO ₂)	21-30
Methane (CH ₄)	8-11
Ethylene (C ₂ H ₄)	2-4

Gasification is the thermochemical conversion of biomass into gaseous fuels by means of partial oxidation of the biomass at high temperatures. The low calorific gas (low heat content gas) that is produced can be fired directly or be used for firing engines and gas turbine cycles and can also serve as syngas in the production of chemicals (e.g., methanol). Gasification is not a new technology; however, its use for the conversion of biomass into a viable fuel has only been investigated for the past thirty years. Production of synthesis gas, or syngas, from biomass can be accomplished by two broad categories of the chemical and thermal processes, namely catalytic routes and noncatalytic processes. Typically, noncatalytic processes require a high temperature of operation – as high as 1,300°C (2,370°F) – whereas catalytic processes can be operated at substantially lower temperatures. With advances in catalysis, the temperature requirement is expected to be reduced even further.

Two reactor types exist: (i) the fluidized bed reactor, which is used with large-scale gasification system, and (ii) the fixed bed reactor, which is employed for small-scale producer gas systems. There are three varieties of fixed bed reactor: (i) the updraft reactor, (ii) the downdraft reactor, and (iii) the crossdraft reactor. Each reactor type produces a different ratio of gases at different temperatures.

In the fluidized bed system, fluidizing gas and heat for the gasification can be supplied by the combustion of a hydrocarbon such as natural gas (methane) or propane in the absence of air. The particulates and char are removed using a high temperature cyclone.

The most common method of gasifying biomass is using an air-blown circulating fluidized bed gasifier with a catalytic reformer, even though there are many different variations. Most fluidized bed gasification processes use closed-coupled combustion with little or no intermediate gas cleaning. This type of process is typically operated at around 900°C (1,650°F), and the product gas from the gasifier contains hydrogen, carbon monoxide, carbon dioxide, water, methane, olefins, benzene, and tar. Gasification uses oxygen (or air) and steam to help the process conversion, just as coal gasification. While the effluent gas from the fluidized bed gasifier contains a decent amount of syngas compositions, the hydrocarbon contents are also quite substantial. Therefore, the gasifier effluent gas cannot be directly used as syngas for further processing for other liquid fuels or chemicals without major purification steps.

Indirect gasification is another gasification process technology that takes advantage of the unique properties associated with biomass. As such, indirect gasification of biomass is substantially different from most coal-based gasification process technologies. For example, biomass is low in sulfur, low in ash, highly reactive, and highly volatile. In an indirect gasification process, biomass is heated indirectly using an external means such as heated sands and a typical gaseous product from an indirect gasifier is close to a medium-Btu gas.

A promising concept is the biomass integrated gasification gasification/combined cycle (BIG/CC) system. Gas turbines can convert gaseous fuel to electricity with a high efficiency. An important advantage of BIG/CC systems is that the gas is cleaned before being combusted in the turbine which means that more compact and less costly gas cleaning equipment is required. The integration ensures high conversion efficiency; on a scale of 30-60 MW_e, net efficiencies of 40-50% (LHV basis of the incoming fuel) can be expected. BIG/CC systems offer a relatively high efficiency on a modest scale. This is important to limit transportation distances for the biomass delivered. A variety of biomass gasification processes are commercially applied.

Another process option for biomass gasification for syngas production involves the use of an entrained flow reactor. This type of process is operated at a high temperature, around 1,300°C (2,370°F), and without use of catalyst. The high temperature is necessary due to the fast reaction rate required for an entrained reactor whose reactor residence time is inherently short.

If a specific biomass feed has high ash content, which is not very typical for biomass, slag can be formed at such a high temperature. Learning from the research developments in coal gasification, a slagging entrained flow gasifier may be adopted for high-ash biomass conversion. Another important process requirement, in addition to high temperature and short residence time, is the particle size of solid feed that must be fine for efficient entrainment as well as for better conversion without mass transfer limit. However, pulverization or milling of biomass is energy-intensive and costly, in general. To facilitate an efficient size reduction of biomass feed, two options are most commonly adopted, viz., torrefaction and pyrolysis.

Production of synthesis gas from biomass by means of gasification also allows for the production of methanol or hydrogen, each of which may have a good future as transportation fuels. For the production of methanol or hydrogen, indirect or oxygen-blown gasification processes are favored because of the medium calorific gas that is produced by such processes.

See Biomass – Pyrolysis, Gasification, Torrefaction.

Biomass – Gasification Principles

The biomass gasification is complex and proceeds primarily through a two-step process, pyrolysis followed by gasification. Pyrolysis is the decomposition of the biomass feedstock by heat. This step, also known as devolatilization, is endothermic and produces 75 to 90% volatile materials in the form of gaseous and liquid hydrocarbon derivatives. The remaining non-volatile material, containing high carbon content is referred to as char. Volatile hydrocarbon and char are subsequently converted to syngas in the second step, gasification.

While pyrolysis begins at temperature in excess of 500°C (930°F), gasification reactions are predominating at temperature nearing and excess of 1,000°C (1,830°F). The following are the details of the reactions during gasification process.

Exothermic Reactions

Endothermic Reactions

See also: Biomass – Gasification.

Biomass – Gasification Process

Biomass gasification is the complete conversion of biomass to gaseous products consisting of carbon monoxide (CO), hydrogen (H₂), and methane (CH₄), with traces of other gases depending on the character of the biomass feedstock.

This gaseous product is usually a low-to-medium Btu gas (producer gas) which can be used to run internal combustion engines (both compression and spark ignition), can be used as substitute for furnace oil in direct heat applications, and can be used to produce, in an economically viable way, methanol – an extremely attractive chemical which is useful both as fuel for heat engines as well as chemical feedstock for industry.

Since any biomass material can undergo gasification, this process is much more attractive than ethanol production or biogas where only selected biomass materials can produce the fuel.

The preliminary gasification of biomass in (preferably) pressurized circulating fluidized bed reactor with secondary processing of the obtained product gas in a slagging entrained flow gasifier is another option. Usually, little or no pretreatment of the biomass is needed (particle size up to 5 cm is acceptable) and that a wide range of biomass feedstock can be processed.

Similar to pyrolysis, the availability of some bed material in the product gas, which is fed into the entrained flow gasifier, is not a concern either, as it improves the properties of molten slag.

Maintaining the stability of the feed flow necessary for the safe operation of entrained flow gasifiers could be a problem, because circulating fluidized bed gasifiers are characterized by some variations in the product gas flow. In order to keep the amount of nitrogen in the product gas under control, the first step circulating fluidized bed gasification is performed with steam, not with air.

After being pyrolyzed in a low-temperature gasifier, biomass pyrolysis gas and char are fed to an entrained flow gasifier and a tar-free gas with high content of carbon monoxide and hydrogen is obtained. The clean gas is cooled down to approximately 200°C (390°F) in a heat exchanger, increasing thereby the overall energy efficiency of the process by producing high-quality steam for power and/or heat generation. Next, the gas is cleaned from dust particles (in a de-duster) and from components, other than carbon monoxide and hydrogen (in a washer). At the end, clean synthesis gas, consisting of carbon monoxide, is obtained. Sufficient gas cleaning represents a key point in syngas and liquids production.

The catalysts for the synthesis of liquid fuels and chemicals are easily poisoned even by small amounts of alkali metals, halides, sulfur compounds, and carbon dioxide which therefore have to be removed to ppm and even ppb levels.

Besides torrefaction, pyrolysis, and pre-gasification, there is a fourth option to convert biomass into a semi-finished material. This is the hydrothermal upgrading process (HTU process), which, under certain conditions, could be considered also as a pre-treatment alternative for biomass conversion.

See also: Biomass – Gasification, Carbo-V Process, Hydrothermal Upgrading Process, Torrefaction.

Biomass – Gasification Reactors

Biomass gasifiers can be classified in to three major groups which are (i) fixed bed reactors, comprising either updraft or downdraft mode, (ii) bubbling fluidized bed reactors, and (iii) circulating fluidized bed reactors.

The difference among each of the reactors is based on the means of supporting the biomass in the reactor vessel, the direction of flow of the biomass, the oxidant, and the way heat is supplied to the reactor. The fixed bed gasifiers are the oldest and simplest form of gasifiers. Although they are a simple, low-cost process, they are not suitable for large-scale production and limited to small-scale operations.

Large-scale biomass gasifiers employ one of two types of fluidized bed configurations: (i) the bubbling fluidized bed and (ii) the circulating fluidized bed or (iii) combination of both (indirectly fired) to maintain the bed temperature below the ash fusion temperature of the biomass ash.

Bubbling Fluidized Bed Gasifier

A bubbling fluidized bed consists of fine, inert particles of sand or alumina, which are selected based on their suitability of physical properties such as size, density, and thermal characteristics. The gas flow rate is chosen to maintain the bed in a fluidization condition, which enters at the bottom of the vessel. The dimension of the bed at some height above the distributor plate is increased to reduce the superficial gas velocity below the fluidization velocity to maintain the inventory of solids and to act as a disengaging zone. A cyclone is used to trap the smaller size particle that exit the fluidized bed, either return fines to the bed or to remove ash rich fines from the system.

Biomass is introduced either through a feed chute to the top of the bed or deep inside the bed. The deeper introduction of biomass into the bed of inert solids provides sufficient residence time for fines that would otherwise be entrained in the fluidizing gas. The biomass organics pyrolytically vaporize and are partially combusted in the

bed. The exothermic combustion provides the heat to maintain the bed temperature and to volatilize additional biomass.

The bed needs to be preheated to the startup temperature using hydrocarbon resources such as natural gas and fuel oil, either by direct firing or by indirect heating. After the bed reaches the biomass ignition temperature, biomass is slowly introduced into the bed to raise the bed temperature to the desired operating temperature which is normally in the range of 700 to 900°C (1,290 to 1,650°F). Bed temperature is governed by the desire to obtain complete devolatilization versus the need to maintain the bed temperature below the biomass ash fusion temperature. The advantages of the fluidized bed gasifiers are: (i) yield of a uniform product gas, (ii) able to accept a wide range of fuel particle sizes, including fines, (iii) exhibits a nearly uniform temperature distribution throughout the reactor, (iv) provides a high rate of heat transfer between inert material and biomass, aiding high conversion, with low tar. The disadvantage is formation of large bubbles at higher gas velocities, which bypass the bed reducing the high rate of heat/mass transfer significantly.

Circulating Fluidized Bed Gasifier

In a circulating fluid bed (CFB) the turbulent bed solids are collected, separated from the gas, and returned to the bed, forming a solids circulation loop. A circulating fluidized bed can be differentiated from a bubbling fluidized bed in that there is no distinct separation between the dense solids zone and the dilute solids zone. Lower bed density can be achieved with increase in gas flow rates in excess of transport velocity of the fluidized bed particles. The residence time of the solids in the circulating fluid bed is determined by the solids circulation rate, attrition of the solids, and the collection efficiency of the solids in the cyclones. The advantages of the circulating fluidized bed gasifiers are that they are (i) suitable for rapid reactions, (ii) high conversion rates possible with low tar and unconverted carbon, and (iii) high heat transport rates possible due to high heat capacity of bed material. The disadvantages are (i) temperature gradients occur in the direction of the solid flow, (ii) the size of fuel particles required to determine minimum transport velocity, (iii) high velocities may result in equipment erosion, and (iv) heat exchange less efficient than in the bubbling fluidized bed reactor.

Indirectly Heated Gasifier

The fluidizing media for the biomass gasification are either air and steam or pure oxygen and steam. Air-blown or directly heated gasifiers use the exothermic reaction between the oxygen and organics to provide the heat necessary to devolatilize biomass and to convert residual carbon rich chars. For directly heated gasifiers, the heat to drive the process is generated inside within the gasifier. When air is used, the product gas is diluted with nitrogen and typically has a dry basis calorific value of 110 to 160 Btu/ft³. The use of oxygen instead of air produces a medium heating value syngas, 265 to 400 Btu/ft³, suitable for combustion turbine application.

Oxygen production is expensive, and hence indirectly heated gasifiers which utilize twin bed concept similar to fluid catalytic crackers (FCC) that are being used in crude oil refining are being developed for generation of medium calorific syngas using air as fluidizing medium.

The syngas produced from the indirectly heated gasifiers is devoid of the nitrogen contamination, and hence they are also favored for other gas- to liquid-based technologies. The non-requirement of oxygen to generate medium heating value syngas, results in lower capital cost for the gasification plant.

If the gas turbines using fossil fuel (natural gas or diesel) which has heating value of approximately 885 Btu/ft³, needs to be interchangeable with the biomass syngas, higher heating values are preferred. In a natural-gas-fired turbine, the gas is only related to 2% v/v of the flow and the rest is air for dilution and combustion, while in contrast, syngas accounts for 14 to 16% v/v of the total gas.

The IGCC (Integrated Gasification Combined Cycle) uses air as the gasifying agent and requires modified turbine combustors to handle the low heating-value gas (110 to 190 Btu/ft³). The low calorific syngas up to 135 Btu/ft³ is only suitable for firing in the boiler or use in diesel engines.

Indirectly heated gasifiers in general generate syngas with a high percentage of hydrogen, methane, and C₂₊ compounds which directly contribute for the higher heating value of the syngas.

Similarly for the directly fired gasifiers, the higher range of hydrogen, methane, and C₂₊ components corresponds to the combustion using oxygen, leading to higher calorific value of the syngas. The absence of nitrogen (inert) in the

system largely helps to concentrate the composition of syngas with higher heating value components. Production of tars, chars, and volatile alkalis are problems associated with gasification which requires further cleaning before it is utilized in turbines for power generation.

The product stream at high pressure and temperature needs to be cleaned under hot conditions not lower than 540°C (1005°F) (tar dew point) in order to maximize the energy conversion efficiency. Thus, a hot cleanup system is required, for which either catalytic tar crackers or a thermal tar cracker could be utilized. A catalytic tar reformer will operate at temperatures comparable to gasifier temperature of 825°C (1,515°F), while a thermal cracker will typically operate at 870 to 980°C (1600 to 1,795°F). After the tar reformer/cracker, the product gas will be partially cooled to minimize the amount of alkali vapors, typically to 350 to 650°C. The product will then pass through a filter to remove solids. As gas turbine application limits the alkali to less than 25 ppb, much of alkali as well needs to be removed.

See also: Synthesis Gas Quality.

Biomass – Herbaceous

Herbaceous biomass is biomass from plants that have a nonwoody stem and which die back at the end of the growing season. This biomass includes most agricultural crops and grasses, including bamboo and wheat straw. Also, relatively young and essentially nonwoody parts of trees exhibit similar characteristics. In general, herbaceous biomass will have higher nutrient contents and lower lignin contents than wood. Herbaceous biomass is variable in composition depending on the time of year and on the type of tissue. Composition can also be strongly influenced by the availability of minerals or nutrients in the soil.

Herbaceous biomass is classified into cereal crops, pastures, oilseed crops, tubers and legumes, flowers, herbaceous biomass of gardens, parks, pruning, vineyards, orchards, and mixtures of all these. This biomass can be used raw (direct residues of the field) or processed (from the food industry).

Residues from cereal crops include the use of the following parts of the plant: dried stems, pods, and husks, as well as their mixtures. Of the grasslands are considered stems, shells, and their mixtures. In oil crops, stems, leaves, pods, rinds, and their mixtures are considered. The residues of the tuber crops are integrated by stems, leaves, roots, and mixtures of these. The stems, leaves, pods, and their mixtures can be harvested from legume crops, but it should be noted that the incorporation of legumes in an annual biomass cultivation system could reduce the nitrogen fertilizer requirements, which will reduce the inputs of bioenergy production. However, they also contribute to the anthropogenic emissions of nitrous oxide (NO₂) which, in this case, nitrous oxide comes mainly from the decomposition of legume residues.

Finally, from the cultivation of flowers, the waste from the plant (when the quality of these is not adequate), the stems, leaves, as well as their mixture can be used. For its part, processed residues can come from herbaceous residues without chemical treatment, as well as chemically treated herbaceous residues and its mixtures. This type of biomass is used mainly in combustion and co-combustion systems, where the technology is well developed, has high efficiency, and low emissions; nevertheless, herbaceous crops that have a high content of potassium which may be detrimental for biomass combustion equipment. It is also used, albeit to a lesser extent, in gasification systems in mixtures with other sources of biomass.

The most abundant form of herbaceous biomass in the world, particularly in European countries, is straw, which is obtained during the annual production of cereals in a proportion of 0.6 to 0.8 tons of straw per ton of grain in the field. In countries where crop productivity is high (in the order of 8 to 10 tons of grain per hectare), the amount of straw per hectare can be between 6 and 8 tons and much of it has been removed for the next crop cycle.

Herbaceous biomass contains variable amounts of cellulose, hemicellulose, and lignin, and a small amount of other extractive, usually perennial, with looser fibers. The relative proportions of cellulose and lignin is one of the determining factors to identify the suitability of plant species for further processing as energy crops (Table B-21).

Table B-21 Approximate composition of herbaceous biomass gas from different sources.

Properties	Herbaceous biomass type	
	Wheat straw	Barley straw
Moisture (% w/w)	16	30
Volatile material (% w/w)	59	46
Fixed carbon (% w/w)	21	18
Ash (% w/w)	4	6
Net calorific value (MJ/kg)	18.6	16.1
C (% w/w)	48.5	45.7
H (% w/w)	5.5	6.1
O (% w/w)	3.9	38.3
N (% w/w)	0.3	0.4
S (% w/w)	0.1	0.1

Switchgrass, a type of fine-stemmed herbaceous biomass, has been used in the United States as a herbaceous cultivation model, has a calorific value comparable to that of wood, but with a lower moisture content; it also has a low content of ash and alkalis, indicating that it could be an adequate fuel for combustion. The main difficulty of this type of biomass is the production of slag at the time of gasification, associated with the ash content. To avoid slag production, the temperature can be reduced, but this results in the loss of carbon. The gas formed in the gasifier contains impurities such as particles, tar, nitrogen compounds, sulfur compounds, and alkaline compounds.

See also: Biomass.

Biomass – Land Requirements

If biomass is to play a major role in the energy supply of the world, energy farming is required. However, it is uncertain whether fallow land will be available to produce biomass for energy instead of food. The main stimulus in the European Union and the United States for introducing non-food crops in agriculture is the surplus production of food. Worldwide food demand is expected to increase considerably, but the amount and type of food that will be required depend on many factors. Population growth, as well as increasing incomes, may result in shifts to more protein-rich diets; both lead to increased demand for food crops. Loss of agricultural land caused by erosion, limited water resources and the increased demand for land for urbanization, infrastructure, and also preservation of nature all limit the possibilities for energy crops.

The availability of land for energy farming, however, does not depend only on the availability of agricultural land. Degraded land, for instance, which is not really suitable for food crops can represent a large potential for energy farming. At the same time, energy crops may help restore these damaged soils. Yields, however, will generally be lower than from good quality land.

Land that is needed to grow energy crops competes with land used for food and wood production unless surplus land is available. Furthermore, the demand for biomass (especially woody biomass) as a renewable energy source has increased continuously in recent years, especially for the direct provision of heat and power generation. However, the biomass potential is limited due to technical constraints and ecological restrictions, as well as the sustainability principles of land management, leading to a predicted supply shortfall.

To avoid competition with food and feed production land, there is the need to establish marginal sites with low soil quality, but sufficient water availability. Tree species capable of stump sprouting, such as poplar, willow, and black locust, can attain high biomass increments on cropland with low soil quality, but sufficient water supply due to their low nutrient requirements and deep-reaching roots. For example, sites for biomass production can be established on cropland with a low depth-to-groundwater table that poplars or willows with deep-reaching roots can utilize, but is inaccessible to annual cultures. The annual crop yield is typically low on croplands with low soil quality. Therefore,

these lands can be seen as agricultural marginal sites, where the combination of yields and prices barely covers the cost of production.

There is the need to conduct an assessment of the potential for land use based on (i) hydrological and climatic conditions, (ii) restrictions by various boundaries, from the technical, ethical, and ecological standpoints, and (iii) energy potential, considering the effect of global climate change.

See also: Biomass.

Biomass – Liquefaction

Biomass liquefaction is the conversion of solid (cellulosic) biomass materials to oil. During the mid-to-late 1980s, commercial interest of the thermochemical conversion of biomass focused on liquefaction. Unlike the initial gasification studies, the preliminary liquefaction studies utilized woody biomass, or lignocellulose material, as the feedstock. Woody biomass was considered superior to that of corn stover due to its potentially lower cost and greater availability.

Pyrolysis is the process of heating biomass in the lack of oxygen or in the presence of a limited amount of oxygen. The pyrolysis oil can be used directly as a fuel or as an intermediate for production of chemicals.

Fast pyrolysis is a thermal decomposition process operating at moderate temperatures (450 to 600°C, 840 to 1,110°F), with high heat transfer rates to the biomass particles and a short residence time. Under these conditions, organic vapors, gases, and char are produced. A short residence time is required to obtain the maximum yield of the liquid.

The vapors are condensed to produce pyrolysis oil (often referred to as bio-oil). Yields of liquid products as high as 79% of the initial dry weight of the biomass can be achieved. Generally, the process produces little or no waste and either the pyrolysis gas or charcoal is used to heat the reactor and the other can be used to supplement the other in heating, dry the feedstock, the charcoal can be sold as a byproduct, or the pyrolysis gas can be used to fuel a gas engine.

Pyrolysis oil is greenhouse gas neutral, does not produce SO_x (sulfur dioxide) emissions and produces approximately half of the NO_x (nitrogen oxide) emissions compared to fossil fuels.

See also: Biofuels, Biomass, Biomass – Liquefaction, Biomass To Liquids, Torrefaction.

Biomass Power

Biomass power is carbon-neutral electricity generated from renewable organic waste that would otherwise be dumped in landfills, openly burned, or left as fodder for forest fires. When burned, the energy in biomass is released as heat.

See also: Biomass Energy, Biomass to Energy.

Biomass – Power Facility

Feedstock requirements for a biomass power facility are dependent upon the capacity of the facility and, to a lesser extent, the efficiency of a specific technology. Dramatic reductions in demand, on a normalized basis, are achievable with increased size of the facility. A 5-MW direct combustion (stoker) power plant has a much higher heat rate than a larger facility. Indeed the larger plant may be approximately 50% more efficient than the smaller installation. The major reason for the higher efficiencies at larger sizes is the increased temperature and pressure that can be economically accommodated in the big facilities to supply larger turbines.

Fuel characteristics greatly affect the combustion process and therefore the decision process for choosing combustion technologies. The most common problems associated with the direct combustion of wood are boiler slagging and fouling, erosion and corrosion, combustion instability, and particulate carryover.

Fuel characteristics that should be analyzed include heating value, moisture content, ash content, sodium and potassium quantities, particle size distribution, ash fusion temperature, and sulfur content. Physical fuel characteristics such as density and particle size affect combustion as well as material handling considerations. Changes in fuel density could cause combustion to occur in the wrong place in the boiler, upsetting the heat transfer scheme and therefore the boiler efficiency.

Biomass Properties

The properties of biomass that have a significant bearing on its thermal conversion are its relatively high moisture, oxygen, hydrogen, and volatile matter content, and low heating value. The high oxygen and hydrogen contents account for the high proportion of volatile matter and consequent high yields of gases and liquids on pyrolysis. A relatively high water yield results from the high oxygen concentration in biomass, and which consumes considerable hydrogen. Consequently, the advantages of the high H/C ratio associated with biomass are not reflected in the products to the extent that might be expected. In fact, pyrolysis gases can be deficient in pure hydrogen and pyrolysis liquids are highly oxygenated, viscous tars.

An additional and significant source of water vapor in biomass gases is the high moisture content of the source materials. In countercurrent flow schemes such as the Lurgi moving bed gasifier, this water is evolved in the relatively low temperature drying and pyrolysis zones and does not partake in gas phase or carbon-steam gasification reactions.

On the other hand, in fluidized bed systems, the moisture is evolved in the high- temperature well-mixed reaction zone and therefore does participate in the reactions. If the system is directly heated and air-blown, the additional heat required to evaporate the water will result in more nitrogen being introduced, and more carbon dioxide being produced, so reducing the calorific value of the product gas. As the gas from air-blown processes is, in any case, a low-calorific value product, this factor is probably of little consequence other than with very wet feedstock. In oxygen-blown systems, however, the additional pure oxygen required and higher carbon dioxide content of the medium calorific value off-gas may be of sufficient impact to dictate some degree of drying as a pretreatment.

Apart from drying, additional beneficiation may be undertaken to yield a resource of higher energy density. These operations will normally be undertaken at the source, so transport and subsequent storage costs may be reduced as well. Beneficiation steps include size reduction and densification. Waste heat, if available, may be used for drying, while size reduction and compression to form pellets or briquettes is estimated to require less than 2% of the energy in the dry biomass. Nevertheless, these operations are time consuming, and can be either labor or capital intensive.

Some advantages of biomass over conventional fossil fuels are the low sulfur content and highly reactive char. In addition, biomass materials do not cake and can therefore be easily handled in both fluidized and moving bed reactors. Finally, catalyst poisons are not present in biomass in significant concentrations. This can be important for the initial thermal processing as well as for subsequent upgrading operations.

Biomass – Pyrolysis

Biomass can be converted into gas, liquid, and char via pyrolysis (Table B-22). The exact proportion of the end products is dependent on the pyrolysis process parameter, such as the feedstock, the temperature, the pressure, and the residence time in the reaction zone). Thus, in fact, pyrolysis of biomass is an important process option, either as a pretreatment for gasification or as an independent process treatment. Pyrolysis takes place actively at a temperature on the order of 500°C (930°F) and produces gases and a liquid product (bio-oil). In fact, the pyrolysis of biomass is quite similar, as a process treatment, to oil shale pyrolysis and coal pyrolysis.

Table B-22 A general flow scheme for biomass conversion by pyrolysis.

Feedstock	Process	Products (primary)	Products (secondary)
Biomass →	550°C/no oxygen	Char	Heat
			Power generation
	Condensation	Vapors	Hydrogen
			Chemicals
		Liquids	Fuels
			Chemicals

Bio-oil production via biomass pyrolysis is typically carried out via flash pyrolysis. The produced oil can be mixed with char to produce a bio-slurry, which can be more easily fed to the gasifier for efficient conversion. The slurry is pumpable and alleviates technical difficulties involved in solid biomass handling.

Typical end products are pyrolysis oil, char, and gas. The oil and char are more economical to transport than the original biomass feedstock and have heating values on the order of 10,000 Btu/lb and 12,000 Btu/lb, respectively. The pyrolysis gas, which has a nominal heating value of 150 Btu/scf, is not considered an end product since it is directly used in the cogeneration system.

The conversion of biomass to crude oil can have an efficiency of up to 70% for flash pyrolysis processes. The bio-oil (biocrude) can be used in engines and turbines and has the potential to be used as a refinery feedstock, although issues need to be overcome. These include poor thermal stability and corrosivity of the oil. Upgrading by lowering the oxygen content and removing alkalis by means of hydrogenation and catalytic cracking of the oil may be required for certain applications.

See also: Biofuels, Biomass, Biomass – Liquefaction, Torrefaction.

Biomass – Synthesis Gas Production

Gasification is the process of gaseous fuel production by partial oxidation of a solid fuel. This means in common terms to burn with oxygen deficit. The gasification of coal is well known, and has a history back to year 1800. The oil-shortage of World War II imposed an introduction of almost a million gasifiers to fuel cars, trucks, and busses. One major advantage with gasification is the wide range of biomass resources available, ranging from agricultural crops, and dedicated energy crops to residues and organic wastes. The feedstock might have a highly various quality, but still the produced gas is quite standardized and produces a homogeneous product. This makes it possible to choose the feedstock that is the most available and economic at all times.

Gasification occurs in a number of sequential steps: (i) drying to evaporate moisture, (ii) pyrolysis to give gas, vaporized tars or oils and a solid char residue, and (iii) gasification or partial oxidation of the solid char, pyrolysis tars and pyrolysis gases.

Not all the liquids from the pyrolysis are converted to syngas, due to physical limitations of the reactor and chemical limitations of the reactions. These residues form contaminant tars in the product gas, and have to be removed prior to a Fischer-Tropsch reactor. Other impurities in the producer gas are the organic BTX [benzene, toluene and xylene (benzene components with one or two methyl groups attached)], and inorganic impurities as NH_3 , HCN , H_2S , COS and HCl . There are also volatile metals, dust, and soot. The tars have to be cracked or removed first, to enable the use of conventional dry gas cleaning or advanced wet gas cleaning of the remaining impurities. There are mainly three ways of tar removing/cracking: thermal cracking, catalytic cracking, or scrubbing.

Despite the long experience with gasification of biomass, there are some problems with large-scale reliable operation. No manufacturer of gasifier is willing to give full guarantee for the technical performance of their gasification technology. Though they are sold commercially, they are not delivered with the same kind of operational guarantee as e.g., a gas turbine. This shows the limited operational experience and lack of confidence in the technology, but in comparison with alternative routes to utilize cellulosic biomass gasification is well proven and one of the possible technologies to be introduced commercially as a major part of the energy route to biofuel.

The production of high-quality syngas from biomass, which is later used as a feedstock for biomass-to-liquids production, requires particular attention. This is due to the fact that the production of synthesis gas from biomass is indeed the novel component in the gas-to-liquids concept – obtaining syngas from fossil raw materials (natural gas and coal) is a relatively mature technology.

Various gasification concepts have been developed over the years, mainly for the purposes of power generation. However, efficient biomass-to-liquids production imposes completely different requirements for the composition of the gas because for power generation, the gas is used as a fuel, while in biomass-to-liquids processing, it is used as a chemical feedstock to obtain other products. This difference has implications with respect to the purity and composition of the gas.

The calorific value of the gas is the prime factor for power generation – the higher the value, the better. Hence, the availability in the gas of any compounds that increase calorific value is generally welcomed – product gas, which contains carbon monoxide (CO), hydrogen (H_2) and various hydrocarbon derivatives [methane (CH_4), ethylene ($CH_2=CH_2$), ethane (C_2H_6), tar, and char]. The presence of inert components [water (H_2O), carbon dioxide (CO_2), and nitrogen (N_2)] is also acceptable, provided it is kept within certain limits. In contrast, for biomass-to-liquids production, the amount of carbon monoxide and hydrogen is important. The presence of other hydrocarbon derivatives and inert components should be avoided or at least kept as low as possible.

The amount of components (primarily hydrocarbon derivatives) other than carbon monoxide and hydrogen can be reduced via their further transformation into carbon monoxide and hydrogen. This is, however, rather energy intensive and costly (two processes – gasification and transformation). As a result, the overall energy efficiency of syngas production and of biomass-to-liquids processing is also reduced.

The amount of various components can be minimized via a more complete decomposition of biomass, thereby preventing the formation of undesirable components at the gasification step. This approach seems to be more appropriate for energy efficiency. The minimization of the content of various hydrocarbon derivatives is achieved by increasing temperatures in the gasifier, along with shortening the residence time of feedstocks inside the reactor. Because of this short residence time, the particle size of feedstocks should be small enough (in any case – smaller than in gasification for power generation) in order that complete and efficient gasification can occur.

In gasification for power generation, typically, air is employed as an oxidizing agent, as it is indeed the cheapest among all possible oxidizing agents. However, the application of air results in large amounts of nitrogen in the product gas, since nitrogen is the main constituent of air. The presence of such large quantities of nitrogen in the product gas does not hamper (very much) power generation, but it does hamper liquids production. Removing this nitrogen via liquefaction under cryogenic temperatures is extremely energy intensive, reduces substantially the overall biomass-to-liquids energy efficiency, and increases costs. Among other potential options (steam, carbon dioxide, carbon monoxide), from a techno-economic point of view, oxygen appears to be the most suitable oxidizing agent for biomass-to-liquids manufacturing.

The air-blown direct gasifiers operated at atmospheric pressure and used in power generation – fixed bed updraft and downdraft and fluidized bed bubbling and circulating – are not suitable for biomass-to-liquids production. In addition, downdraft fixed bed gasifiers face severe constraints in scaling and are fuel inflexible, being able to process only fuels with well-defined properties.

Updraft fixed bed gasifiers have fewer restrictions in scaling (usually up to 10 MW), but the produced gas contains a lot of tars and methane. However, fluidized bed gasifiers generally do not encounter limitations in scaling and are more flexible concerning the particle size of fuels. Nevertheless, they still have limited fuel flexibility, due to a risk of slagging and fouling, agglomeration of bed material, and corrosion. The operating temperatures of air-blown fluidized bed gasifiers are therefore kept relatively low (800 to 1,000°C, 1,470 to 1,830°F), which implies incomplete decomposition of feedstocks, unless long residence times are used.

Fluidized bed gasifiers (especially the bubbling bed gasifiers) tend to contaminate the product gas with dust. The oxygen-blown atmospheric or pressurized circulating fluidized bed gasifiers and the steam-blown gas or char indirect gasifiers are better solutions for biomass-to-liquids processes. Both gasifying concepts significantly reduce the amount of nitrogen in the product gas. In the first case, it is achieved via substituting air with oxygen. In the second case, nitrogen ends up in the flue gas, but not in the product gas, because gasification and combustion are separated – the energy for the gasification is obtained by burning the chars from the first gasifier in a second reactor.

Nonetheless, both oxygen-blown circulating bed gasifiers and steam-blown indirect gasifiers still present some major weak points with regard to biomass-to-liquids processes. In the former case, the issues related to the necessity for further cracking of the unconverted hydrocarbon derivatives and with the high dust emissions are still relevant. In the latter case, these two drawbacks can be overcome, but at the expense of a significant increase in capital costs, since two reactors are needed instead of just one. In fact, the case of the gas indirect gasifier also involves a second reactor. Finally, indirect gasifiers carry a higher risk of malfunctioning and are less reliable, because of their more sophisticated configuration.

Considering the above reasons, the pressurized oxygen-blown direct entrained flow gasifier appears to be the most suitable gasification concept to obtain synthesis gas for later biomass-to-liquids processes. Entrained flow gasifiers do not encounter severe scaling restrictions, and their capacity can easily be of several hundred MW. They also represent a mature technology for coal (not for biomass!), which has been employed for years. Entrained flow gasifiers operate at elevated pressures and much higher temperatures (1,200 to 1,500°C, 2,190 to 2,730°F) than other gasifiers (usually below 900°C, 1,650°F). The residence time of the fuel is also much shorter (a few seconds) compared to that in other gasifiers.

For a complete transformation of the feedstock into synthesis gas within such short residence time, its particle size also has to be smaller than that required for other gasifiers – not larger than 1 mm, typically below 0.1 mm (100 µm, 100 microns). With such extreme conditions, almost tar-free synthesis gas with high content of carbon monoxide and hydrogen is obtained. This high conversion rate is also facilitated by the high reactivity and volatility of biomass. Conversely, the maximization of the liquids yield, i.e., of the content of CO and H₂ in the product gas, results in 10 to 15% lower total transformation efficiency (when other useful products from gasification are also counted) compared to other gasifying concepts.

Many feedstocks have high content of ash, which under high temperature turns into molten slag. Molten slag also retains some undesirable compounds of biomass, e.g., heavy metals. The removal of molten slag from the bottom of the reactor has to be incorporated into its design – a slagging-type entrained flow gasifier. In order to improve slag properties, the addition of fluxing material (silica sand or limestone) is necessary. In contrast, in non-slugging entrained flow gasifiers, the removal of molten slag is not foreseen. Hence, non-slugging gasifiers are fuel inflexible, suitable only for clean feedstocks with low mineral (ash) content (less than 1%), e.g., oils.

The energy efficiency of gasification is further reduced by the removal of large quantities of inert gas (usually carbon monoxide) from the product gas. Inert gas is employed as a medium for lock hopper pressurization and pneumatic feeding of pulverized material (a mandatory feeding option for finely pulverized fuels) into the reactor. The amount of inert gas depends on the bulk density of fuels – the lower the density, the larger the amount. The low bulk density of biomass implies large consumption of carbon dioxide, and alternative forms of biomass feedstock (via pre-treatment) have to be considered for entrained flow gasifiers. The most feasible biomass pre-treatment options are torrefaction, pyrolysis, and pre-gasification.

Biomass to Energy

The old way of converting biomass to energy, practiced for thousands of years, is simply to burn it to produce heat (one of final forms of energy). The problems with burning biomass are that much of the energy is wasted and that it can cause some pollution if it is not carefully controlled. A number of non-combustion methods are available for converting biomass to energy. These processes convert raw biomass into a variety of gaseous, liquid, or solid fuels that can then be used directly in a power plant for energy generation. The carbohydrates in biomass, which are comprised of oxygen, carbon, and hydrogen, can be broken down into a variety of chemicals, some of which are useful

fuels. This conversion can be done in three ways: (i) thermochemical methods, (ii) biochemical methods, and (iii) physical methods.

When plant matter is thermally decomposed, it breaks down into various gases, liquids, and solids. These products can then be further processed and refined into useful fuels such as methane and alcohol. Biomass gasifiers capture methane released from the plants and burn it in a gas turbine to produce electricity. Another approach is to take these fuels and run them through fuel cells, converting the hydrogen-rich fuels into electricity and water, with few or no emissions.

Biochemical methods of biomass breakdown involve the use of bacteria, yeasts, and enzymes, which also break down carbohydrates. Fermentation, the process used to make wine, changes biomass liquids into alcohol, a combustible fuel. A similar process is used to turn corn into grain alcohol or ethanol, which is mixed with gasoline to make gasohol. Also, when bacteria break down biomass, methane and carbon dioxide are produced. This methane can be captured, in sewage treatment plants and landfills, for example, and burned for heat and power.

Biomass oils, like soybean and canola oil, can be chemically converted into a liquid fuel similar to diesel fuel, and into gasoline additives. Cooking oil from restaurants, for example, has been used as a source to make biodiesel for trucks.

See also: Biofuels, Biochemical Platform, Biomass Conversion, Thermochemical Platform.

Biomass to Liquids

The biomass-to-liquid (BTL) process concept is a process for converting various types of biomass to liquid fuels and uses a variety of processes (Table B-23).

Table B-23 Conversion of biomass to fuels.

Pretreatment		
Vegetable oil		
Esterification		
Biodiesel		

There are two types of biomass feedstock that can be employed to produce BTL fuels – woody and herbaceous. Woody feedstock comprises wood chips, wood powder and sawdust, obtained from ordinary forestry (wood logs), short-rotation forestry, various wood residues, and wood waste. Herbaceous feedstock includes chaffed dedicated energy crops and straw.

Owing to biomass composition, woody feedstock is better suited for energy applications than herbaceous feedstock. Woody biomass also has a larger production potential for energy (including BTL) application; however, the production potential of herbaceous biomass is currently under-explored as the path to useful products is open, for example (Table B-24):

Table B-24 Routes to liquid fuels from biomass.

						Gasoline

Biomass pyrolysis is a process by which a biomass feedstock is thermally degraded in the absence of air/oxygen. It is used for the production of solid (charcoal), liquid (tar and other organics), and gaseous products. These products are of interest as they are possible renewable sources of energy. The study of pyrolysis is gaining increasing importance, as it is not only an independent process but it is also a first step in the gasification or combustion process, and has many advantages over other renewable and conventional energy sources. The actual reaction scheme of pyrolysis of biomass is extremely complex because of the formation of over a hundred intermediate products.

Plasma pyrolysis provides high temperature and high energy for reaction as the reaction sample is rapidly heated up to a high temperature. This review also covers the experimental and modeling study status of plasma-assisted pyrolysis.

Biofuels produced via gasification routes include direct gasoline and diesel substitutes made from gas-to-liquid processes (i.e., the Fischer-Tropsch process), methanol, ethanol, mixed alcohols, and hydrogen. Gas-to-liquids technologies are utilized commercially using natural gas or stranded natural gas as feedstock. Coal was used extensively by Germany in WWII and is still used in the Sasol (South Africa) facilities for gasoline and diesel fuel synthesis along with a wide variety of other products.

In a biomass-to-liquids process, the feedstock undergoes a pretreatment or selection (sizing, drying, and sorting) and is then gasified in a reactor. The gas product (carbon monoxide, hydrogen, low-boiling hydrocarbon derivatives, tars, and particulate material) undergoes extensive cleanup to remove catalyst poisons and other undesirable components. This is followed by gas processing/reforming where the hydrogen/carbon monoxide ratio is adjusted before entering the (Fischer-Tropsch) synthesis reactor. The liquid synthesis reactor contains catalyst material and operates at elevated pressure and temperature forming hydrocarbon compounds or alcohols from the synthesis gas. The liquids can be further refined to the desired end product.

Biomass Waste

Biomass is the material derived from plants that use sunlight to grow which include plant and animal material such as wood from forests, material left over from agricultural and forestry processes, and organic industrial, human, and animal wastes. Biomass comes from a variety of sources which include (alphabetically and not by preference or use):

- Agricultural residues such as straw, stover, cane trash and green agricultural wastes
- Agro-industrial wastes, such as sugarcane bagasse and rice husk
- Animal wastes
- Food processing wastes
- Forestry plantations
- Forestry residues
- Municipal solid wastes (MSW)
- Industrial wastes, such as black liquor from paper manufacturing
- Sewage
- Wood from natural forests and woodlands

The energy contained in biomass originally came from the sun. Through photosynthesis, carbon dioxide in the air is transformed into other carbon-containing molecules (e.g., sugars, starches, and cellulose) in plants. The chemical energy that is stored in plants and animals (animals eat plants or other animals) or in their waste is called bio-energy.

When biomass is burned, it releases its energy, generally in the form of heat. The biomass carbon reacts with oxygen in the air to form carbon dioxide. If fully combusted, the amount of carbon dioxide produced is equal to the amount which was absorbed from the air while the plant was growing.

In nature, if biomass is left lying around on the ground, it will break down over a long period of time, releasing carbon dioxide and its store of energy slowly. By burning biomass, its store of energy is released quickly and often in a useful way. So converting biomass into useful energy imitates the natural processes but at a faster rate.

Biomass wastes can be transformed into clean energy and/or fuels by a variety of technologies, ranging from conventional combustion process to state-of-the-art thermal depolymerization technology. Besides recovery of substantial energy, these technologies can lead to a substantial reduction in the overall waste quantities requiring final disposal, which can be better managed for safe disposal in a controlled manner while meeting the pollution control standards.

Biomass waste-to-energy conversion reduces greenhouse gas emissions in two ways. Heat and electrical energy are generated which reduces the dependence on power plants based on fossil fuels. The greenhouse gas emissions are significantly reduced by preventing methane emissions from landfills. Moreover, waste-to-energy plants are highly efficient in harnessing the untapped sources of energy from wastes.

Biomass energy projects provide major business opportunities, environmental benefits, and rural development. Feedstocks can be obtained from a wide array of sources without jeopardizing the food and feed supply, forests, and biodiversity in the world and include (i) agricultural residues, (ii) animal waste, (iii) forestry residue, (iv) wood waste, (v) industrial waste, (vi) municipal solid waste, and (vii) sewage.

Agricultural residues encompasses all agricultural wastes such as bagasse, straw, stem, stalk, leaves, husk, shell, peel, pulp, stubble, etc. Large quantities of crop residues are produced annually worldwide, and are vastly underutilized. Rice produces both straw and rice husks at the processing plant which can be conveniently and easily converted into energy. Significant quantities of biomass remain in the fields in the form of cob when maize is harvested which can be converted into energy. Sugar cane harvesting leads to harvest residues in the fields, while processing produces fibrous bagasse, both of which are good sources of energy. Harvesting and processing of coconuts produces quantities of shell and fiber that can be utilized. The current farming practice is usually to plough these residues back into the soil, or they are burnt, left to decompose, or grazed by cattle. These residues could be processed into liquid fuels or thermochemically processed to produce electricity and heat. Agricultural residues are characterized by seasonal availability and have characteristics that differ from other solid fuels such as wood, charcoal, and char briquette. The main differences are the high content of volatile matter and lower density and burning time.

Animal waste represents a wide range of biomass that can be used as sources of biomass energy. The most common sources are animal and poultry manures. In the past, this waste was recovered and sold as a fertilizer or simply spread onto agricultural land, but the introduction of tighter environmental controls on odor and water pollution means that some form of waste management is now required, which provides further incentives for waste-to-energy conversion. The most attractive method of converting these waste materials to useful form is anaerobic digestion which gives biogas that can be used as a fuel for internal combustion engines, to generate electricity from small gas turbines, burnt directly for cooking, or for space and water heating.

Forestry residues are generated by operations such as thinning of plantations, clearing for logging roads, extracting stem-wood for pulp and timber, and natural attrition. Harvesting may occur as thinning in young stands, or cutting in older stands for timber or pulp that also yields tops and branches usable for biomass energy. Harvesting operations usually remove only 25 to 50% of the volume, leaving the residues available as biomass for energy. Stands damaged by insects, disease, or fire are additional sources of biomass. Forest residues normally have low density and fuel values that keep transport costs high, and so it is economical to reduce the biomass density in the forest itself.

Wood wastes generated by the wood processing industries primarily include sawmilling, plywood, wood panel, furniture, building component, flooring, particle board, molding, jointing, and craft industries. Wood wastes generally are concentrated at the processing factories, e.g., plywood mills and sawmills. The amount of waste generated from wood processing industries varies from one type of industry to another depending on the form of raw material and finished product. Typically, the waste from wood industries such as saw millings and plywood, veneer, and others are sawdust, off-cuts, trims, and shavings. Sawdust arises from cutting, sizing, re-sawing, and edging, while trims and shaving are the consequence of trimming and smoothing of wood. In general, processing of wood in the furniture industries will lead to waste generation of almost half (45 %) of wood. Similarly, when processing wood in a sawmill, the waste will amount to more than half (52 %) of the wood.

Industrial wastes are generated by the food industry which produces a large number of residues and by-products that can be used as biomass energy sources. These waste materials are generated from all sectors of the food industry with everything from meat production to confectionery producing waste that can be utilized as an energy source. Solid wastes include peelings and scraps from fruit and vegetables, food that does not meet quality control standards, pulp and fiber from sugar and starch extraction, filter sludge, and coffee grounds. These wastes are usually disposed of in landfill dumps.

Liquid wastes are generated by washing meat, fruit and vegetables, blanching fruit and vegetables, pre-cooking meats, poultry and fish, cleaning and processing operations, as well as wine making. These wastewaters contain sugars, starches, and other dissolved and solid organic matter. The potential exists for these industrial wastes to be anaerobically digested to produce biogas, or fermented to produce ethanol, and several commercial examples of waste-to-energy conversion already exist. The pulp and paper industry is considered to be one of the highly polluting industries and consumes a large amount of energy and water in various unit operations. The wastewater discharged by this industry is highly heterogeneous as it contains compounds from wood or other raw materials, processed chemicals, as well as compound formed during processing. Black liquor can be judiciously utilized for production of biogas using anaerobic digestion technology.

Municipal solid wastes are produced and collected each year with the vast majority being disposed of in open fields. The biomass resource in municipal solid waste comprises the putrescible materials, paper, and plastic and averages 80% of the total municipal solid waste collected. Municipal solid waste can be converted into energy by direct combustion, or by natural anaerobic digestion in the engineered landfill. At the landfill sites, the gas produced by the natural decomposition of municipal solid waste (approximately 50% methane and 50% carbon dioxide) is collected from the stored material and scrubbed and cleaned before feeding into internal combustion engines or gas turbines to generate heat and power. The organic fraction of municipal solid waste can be anaerobically stabilized in a high-rate digester to obtain biogas for electricity or steam generation.

Sewage is a source of biomass energy that is similar to the other animal wastes. Energy can be extracted from sewage using anaerobic digestion to produce biogas. The sewage sludge that remains can be incinerated or undergo pyrolysis to produce more biogas.

Bio-oil

Bio-oil (sometimes called bio-crude) is the liquid condensate produced from biomass (forestry residues, crop residues, waste paper, and organic waste) by means of processes such as pyrolysis (thermal and catalytic). Depending on the feedstock, the bio-oil could be compatible with existing refinery technology and can be converted into fuels, such as gasoline, diesel fuel, and jet fuel.

The product can vary from a light tarry material to a free-flowing liquid that is produced by the thermal decomposition (destructive distillation) of biomass at temperatures on the order of 400°C (750°F) (Table B-25).

Table B-25 Examples of the yield of bio-oil by pyrolysis from agricultural residues at different temperatures (°C).

Sample	400	450	500	550	600	650	700	775
Hazelnut shell	38.0	39.5	40.4	41.9	42.2	41.0	39.2	38.5
Tea waste	34.9	35.8	36.0	36.2	38.0	37.0	35.5	33.4
Tobacco stalk	41.0	41.8	43.0	40.2	40.0	40.6	37.3	36.8

Also, the product is of interest as a possible complement (eventually a substitute) to crude oil to produce specification-grade fuels (Table B-26).

Table B-26 Representation of the conversion of biomass into fuels.

Process	Product	Process	Refinery
Pyrolysis			
	Bio-oil	Deoxygenation	
			Gasoline
			Diesel
			Jet fuel

Bio-oil is not a product of thermodynamic equilibrium during pyrolysis but is produced with short reactor times and rapid cooling or quenching from the pyrolysis temperatures. Bio-oils are multi-component mixtures of different size molecules derived from depolymerization and fragmentation of cellulose, hemicellulose, and lignin. Bio-oil is a liquid mixture of oxygenated compounds containing carbonyl, carboxyl, and phenolic functional groups. One of the main drawbacks of the bio-oil is that the composition of the pyrolytic oils is similar to that of the original biomass and is different from crude oil-derived fuels and chemicals (Maher and Bressler, 2007).

Hydrocarbon moieties are predominant in the product, but the presence of varying levels of oxygen (depending upon the character of the feedstock) requires treatment (using for example, hydrotreating) during refining. On the other hand, the bio-oil can be used as a feedstock to the Fischer-Tropsch process for the production of lower-boiling products, as is the case when naphtha and gas oil are used as feedstocks for the Fischer-Tropsch process. In summary, the Fischer-Tropsch process produces hydrocarbon products of different molecular weight from a gas mixture of carbon monoxide and hydrogen (synthesis gas) all of which can find use in various energy scenarios.

In the hydrothermal upgrading process (HTU process), biomass is treated with water at high temperature (300 to 350°C, 570 to 660°F) and pressure 1,770 to 2,650 psi) to produce bio-crude. This can be separated by flashing or by extraction to a viscous oil that is suitable for co-combustion in coal power stations and low-density crude oil, which can be upgraded by hydrodeoxygenation (HDO) to biofuels.

The rapid thermal processing process (RTP™ process) occurs at a temperature of approximately 500°C (930°F), when a turbulent stream of hot sand flashes the biomass into a vapor. The vapor is then rapidly condensed into a liquid. This process occurs in less than two seconds, yielding high quantities of bio-oil (typically 65 to 75% w/w yield of pyrolysis oil from dried lignocellulosic biomass).

Bio-oil is a dark brown viscous liquid that bears some resemblance to fossil crude oil. However, bio-oil is a complex oxygenated compound comprised of water, water-soluble compounds, such as acid derivatives, ester derivative, and water-insoluble compounds, usually called pyrolytic lignin because it comes from the lignin fraction of the biomass. The elemental composition of bio-oil is similar to that of the parent biomass. Because of its high oxygen content, the heating value (Btu per gallon) of bio-oil is lower than fossil fuel, typically only approximately half the heating value of fossil crude such as high-boiling fuel oil. However, it contains less nitrogen and only traces of metals or sulfur.

Bio-oil is acidic with a pH in the 2-4 range, making it highly unstable and corrosive – the acidity can be lessened by the addition of readily available base compounds. It, therefore, presents transportation/piping and storage challenges including the tendency to corrode most metals. Hence, it is usually transported and stored in stainless steel containers. Generally, the properties of bio-oil are variable (Table B-27) and dependent on the feedstock. The specific gravity of the liquid is approximately 1.10 to 1.25, which means it is slightly heavier than water, heavier than fuel oil, and significantly heavier than the bulk density of the original biomass. The viscosity of the oil varies from as low as 25 cP up to 1,000 cP, depending on the water content and the original feedstock.

Table B-27 Typical properties and composition of bio-oil*.

Property	
Water content, % w/w	15 – 35
pH	2.8 – 4.0
Density (kg/L)	1.1 - 1.25
Elemental analysis (moisture free)	
Carbon, % w/w	55 – 64
Hydrogen, % w/w	5 – 8
Nitrogen, % w/w	0.05 – 1
Sulfur, % w/w	0 - 0.05
Oxygen, % w/w	100 - (C + H + N + S)
Ash, % w/w	0.03 - 0.3
Viscosity (42°C, 108°F, cP)	25-1000

*Also called *pyrolysis oil*.

Although freshly made bio-oil can be pumped and transported through pipelines, its viscosity increases with time. Unprocessed bio-oil cannot be readily mixed with crude oil-derived fuels.

Despite the above-mentioned shortcomings, bio-oil has great potential. It can be used as heating oil if proper furnaces can be designed to do so; nitrogen oxide emissions are low when combusted. Additionally, it can be potentially upgraded (or refined) to produce liquid transportation fuels and organic chemicals.

Due to large amounts of oxygenated components present in bio-oil, the oil tends to be polar (like water) and, therefore, does not mix readily with hydrocarbon derivatives or with biodiesel. The degradation products from the biomass constituents include organic acids (like formic and acetic acid), giving the oil its low pH, typically between 2 and 4. Water is also an integral part of the single-phase chemical solution (water-soluble fraction).

The water content of bio-oil is typically 15 to 35% v/v, and the oil has the tendency to phase-separate when the water content reaches the 30 to 45% v/v range. The heating value (i.e., the higher heating value, HHV) is below 11,175 Btu/lb compared to 18,052-18,911 Btu/lb for conventional fuel oils. The high heating values of bio-oil (dry-ash free) of switchgrass (cave-in-rock), corn cob, corn stover (no cobs) and alfalfa stems at early bud are 10,164, 11,249, 10,448, and 14,249 Btu/lb, respectively.

See also: Biomass, Bio-oil Upgrading, Fischer-Tropsch Process, Hydrothermal Upgrading Process.

Bio-oil – Upgrading

Bio-oil produced by the pyrolysis of lignocellulosic materials is among the most complex and inexpensive raw oils that can be derived from biomass and required upgrading prior to use. Typically, bio-oil consists of five major fractions: (i) water, 15 to 30% w/w, (ii) low-boiling oxygenated compounds, 8 to 26% w/w, (iii) phenols derivatives, 2 to 7% w/w, (iv) water-insoluble oligomers derived from lignin, 15 to 25% w/w, and (v) water-soluble products, 10 to 30% w/w.

Upgrading bio-oil to a conventional transport fuel such as gasoline, diesel, gasoline, methane, or liquefied petroleum gas (LPG) requires water removal, deoxygenation (by hydrocracking and/or hydrotreating), followed by product recovery (typically by distillation), which can be accomplished by integrated conventional refinery processes (Table B-28).

Table B-28 Simplified illustration of bio-oil upgrading.

Feedstock	Process (primary)	Product	Process (secondary)	Products
Biomass	Pyrolysis*	Bio-oil		
			Hydrocracking	
			(plus hydrotreating)	Methane
				Naphtha (gasoline)
				Kerosene (diesel)
			Gasification	
			(synthesis gas)	Alcohols
				Hydrocarbons

*Often referred to as thermal cracking in the refining industry.

There is also interest in partial upgrading to a product that is compatible with refinery streams in order to take advantage of the economy of scale and experience in a conventional refinery. Integration into refineries by upgrading through cracking or hydrotreating is a viable option, but in such cases where the bio-oil is blended with a crude oil product, there may be incompatibility issues that arise.

Upgrading bio-oil to a conventional transport fuel such as diesel, gasoline, kerosene, methane, and liquefied petroleum gas (LPG) requires full deoxygenation and conventional refining, which can be accomplished either by integrated catalytic pyrolysis or by decoupled liquid phase hydrodeoxygenation. There is also growing interest in partial upgrading to a product that is compatible with refinery streams in order to take advantage of the economy of scale and experience in a conventional refinery, and the main methods are: (i) hydrodeoxygenation and (ii) catalytic cracking, in situ or ex situ gasification to synthesis gas followed by synthesis to hydrocarbon derivatives or alcohol derivatives.

Hydrothermal liquefaction under a hot-water environment has been proposed as an alternative process to provide better energy efficiency and unique characteristics of bio-oil and other related products compared to pyrolysis-based processes. The optimization of the operating parameters, including temperature, pressure, time, and catalyst, is crucial for improving the performance of these processes. In addition to bio-oil production technologies, several upgrading technologies based on catalytic approaches (e.g., hydrotreatment and esterification) have also been developed to further improve bio-oil quality for a variety of applications.

See also: Bio-oil, Refining.

Bio-oxidation

Bio-oxidation (biological oxidation) is one of the most used methods of desulfurization, based on injection of a small amount of air (2 to 8% v/v) into the raw gas stream. This way, the hydrogen sulfide is biologically oxidized either to solid free sulfur or to liquid sulfurous acid (H_2SO_3):

In practice, the precipitated sulfur is collected and added to the storage tanks where it is mixed with digestate, in order to improve the fertilizer properties of digestate. Biological desulfurization is frequently carried out inside the digester, and, for this kind of desulfurization, oxygen and *Sulfobacter oxydans* bacteria must be present, to convert hydrogen sulfide into elementary sulfur, in the presence of oxygen. Typically, *Sulfobacter oxydans* is present inside the digester (does not have to be added) as the anaerobic digester substrate contains the necessary nutrients for their metabolism. In the process, the air is injected directly in the headspace of the digester and the reactions occur in the reactor headspace, on the floating layer (if existing) and on reactor walls. Due to the acidic nature of the products, there is the risk of corrosion. The process is dependent of the existence of a stable floating layer inside the digester, and the process often takes place in a separate reactor.

Chemical desulfurization of gas streams can take place outside of digester, using a base (usually sodium hydroxide). Another chemical method to reduce the content of hydrogen sulfide is to add commercial ferrous solution (Fe^{2+}) to the feedstock. Ferrous compounds bind sulfur in an insoluble compound in the liquid phase, thereby preventing the production of gaseous hydrogen sulfide.

See also: Biofiltration, Bioscrubbing, Gas Cleaning – Biological Methods Gas Processing, Gas Treating.

Biophotolysis

The photosynthetic production of gas (e.g., hydrogen) hydrogen employs microorganisms such as cyanobacteria, which have been genetically modified to produce pure hydrogen rather than the metabolically relevant substances. The conversion efficiency from sunlight to hydrogen is small, usually under 0.1%, indicating the need for large collection areas.

The current thinking favors ocean locations of the bio-reactors. They have to float on the surface (due to rapidly decreasing solar radiation as function of depth), and they have to be closed entities with a transparent surface (e.g., glass), in order that the hydrogen produced is retained and in order for sunlight to reach the bacteria. Because hydrogen buildup hinders further production, there further has to be a continuous removal of the hydrogen produced, by pipelines to, for example, a shore location, where gas treatment and purification can take place. These requirements make it little likely that equipment cost can be kept so low that the low efficiency can be tolerated.

A further problem is that if the bacteria are modified to produce maximum hydrogen, their own growth and reproduction are quenched. Presumably, there has to be made a compromise between the requirements of the organism and the amount of hydrogen produced for export, so that replacement of organisms (produced at some central biofactory) does not have to be made at frequent intervals. The implication of this is probably an overall efficiency lower than 0.05%.

In a life-cycle assessment of bio-hydrogen produced by photosynthesis, the impacts from equipment manufacture are likely substantial. To this, one should add the risks involved in production of large amounts of genetically modified organisms. In conventional agriculture, it is claimed that such negative impacts can be limited, because of the slow spreading of genetically modified organisms to new locations (by wind or by vectors such as insects, birds, or other animals).

In the case of ocean bio-hydrogen farming, the unavoidable breaking of some of the glass- or transparent plastic-covered panels will allow the genetically modified organisms to spread over the ocean involved and ultimately the entire biosphere. A quantitative discussion of such risks is difficult, but the negative cost prospects of the bio-hydrogen scheme probably rule out any practical use anyway.

Biopower

Biopower (biomass power, renewable electric energy) is the use of biomass feedstock to produce electric power or heat through direct combustion of the feedstock, through biopower system technologies (such as: direct-firing, co-firing, gasification, pyrolysis, and anaerobic digestion), gasification and then combustion of the resultant

gas, or through other thermal conversion processes. Power is generated with engines, turbines, fuel cells, or other equipment.

Most biopower plants use direct-fired systems. They burn bioenergy feedstocks directly to produce steam. This steam drives a turbine, which turns a generator that converts the power into electricity. In some biomass industries, the spent steam from the power plant is also used for manufacturing processes or to heat buildings. Such combined heat and power systems greatly increase overall energy efficiency. Paper mills, the largest current producers of biomass power, generate electricity or process heat as part of the process for recovering pulping chemicals.

Co-firing refers to mixing biomass with fossil fuels in conventional power plants. Coal-fired power plants can use co-firing systems to significantly reduce emissions, especially sulfur dioxide emissions. Gasification systems use high temperatures and an oxygen-starved environment to convert biomass into synthesis gas, a mixture of hydrogen and carbon monoxide. The synthesis gas (syngas) can be converted into other fuels or products, burned in a conventional boiler, or used instead of natural gas in a gas turbine. Gas turbines are very much like jet engines, only they turn electric generators instead of propelling a jet. Highly efficient to begin with, they can be made to operate in a “combined cycle,” in which their exhaust gases are used to boil water for steam, a second round of power generation, and even higher efficiency.

Using a similar thermochemical process but different conditions (totally excluding rather than limiting oxygen, in a simplified sense) will pyrolyze biomass to a liquid rather than gasify it. As with syngas, pyrolysis oil can be burned to generate electricity or used as a chemical source for making plastics, adhesives, or other bioproducts.

The natural decay of biomass produces methane, which can be captured and used for power production. In landfills, wells can be drilled to release the methane from decaying organic matter. Then, pipes from each well carry the methane to a central point, where it is filtered and cleaned before burning. This produces electricity and reduces the release of methane (a very potent greenhouse gas) into the atmosphere.

Methane can also be produced from biomass through a process called anaerobic digestion. Natural consortia of bacteria are used to decompose organic matter in the absence of oxygen in closed reactors. Gas suitable for power production is produced, and possibly troublesome wastes (such as those at sewage treatment plants or feedlots) are turned to usable compost.

Gasification, anaerobic digestion, and other biomass power technologies can be used in small, modular systems with internal combustion or other generators. These could be helpful for providing electrical power to villages remote from the electrical grid—particularly if they can use the waste heat for crop drying or other local industries. Small, modular systems can also fit well with distributed energy generation systems.

Bioprocess

A bioprocess is any process that uses complete living cells or organisms or their components (e.g., bacteria, enzymes) to effect desired a physical change and/or a chemical change in the feedstock. Transport of energy and mass is fundamental to many biological and environmental processes.

Modern bioprocess technology used this principle and is actually an extension of older methods for developing useful products by taking advantage of natural biological activities. Although more sophisticated, modern bioprocess technology is based on the same principle: combining living matter (whole organisms or enzymes) with nutrients under the conditions necessary to make the desired end product. Bioprocesses have become widely used in several fields of commercial biotechnology, such as production of enzymes (used, for example, in food processing and waste management) and antibiotics.

Since bioprocesses use living material, they offer several advantages over conventional chemical methods of production. Bioprocesses usually require lower temperature, pressure, and pH (the measure of acidity) and can use renewable resources (biomass) as raw materials. In addition, greater quantities can be produced with less energy consumption.

In most bioprocesses, enzymes are used to catalyze the biochemical reactions of whole microorganisms or their cellular components. The biological catalyst causes the reactions to occur but is not changed. After a series of such reactions (which take place in large vessels (fermenters or fermentation tanks), the initial raw materials are

chemically changed to form the desired end product. Nevertheless, there are challenges to the use of bioprocesses in the production of synthetic fuels.

First, the conditions under which the reactions occur must be rigidly maintained. Temperature, pressure, pH, oxygen content, and flow rate are some of the process parameters that must be kept at specific levels. With the development of automated and computerized equipment, it is becoming much easier to accurately monitor reaction conditions and thus increase production efficiency.

Second, the reactions can result in the formation of many unwanted by-products. The presence of contaminating waste material often poses a two-fold problem related to (i) the means to recover (or separate) the end product in a way that leaves as little residue as possible in the catalytic system, and (ii) the means by which the desired product can be isolated in pure form.

See also: Bioconversion Platform.

Bioreactor

One of the major areas of research concerning landfill is the use of bioreactors. A bioreactor is formed under specific land filling conditions. Bioreactor land filling is a process in which water and air are circulated into a specially-designed landfill, in order to cause accelerated biological decomposition of the waste material. The intention for this type of landfill operation is to maximize the generation of biogas, which is captured using a network of perforated pipes and burnt to generate electricity. Another desired outcome is the rapid stabilization of organic waste material (in order to minimize the length of time required to manage the landfill site or to make use of the decomposed material as compost).

By adding and recirculating liquids in bioreactors, decomposition is accelerated under anaerobic conditions, increasing the production of landfill gas by 2 to 10 times, approximately half of which is methane with at least 23 times the warming potential as carbon dioxide. The result is to shift substantial volumes of methane production, which otherwise would not occur for decades hence, to the present.

In the landfill, which acts as a bioreactor, anaerobic digestion occurs insofar as the naturally occurring processes of anaerobic degradation are harnessed and contained. Anaerobic digestion has a long history dating back to the 10th century BC and involves four stages which are (i) hydrolysis, (ii) acidogenesis, (iii) acetogenesis, and (iv) methanogenesis. These stages result from the biological treatment of organic waste by two key bacterial groups – acetogens, and methanogens.

The hydrolysis stage is the chemical reaction where complex organic molecules are broken down into simple sugars, amino acids, and fatty acids with the addition of hydroxyl groups. The acidogenesis stage is the process where a further breakdown by acidogens into simpler molecules, volatile fatty acids occurs, producing ammonia, carbon dioxide, and hydrogen sulfide as by-products. The acetogenesis stage is the biochemical process where the simple molecules from acidogenesis are further digested by acetogens to produce carbon dioxide, hydrogen, and mainly acetic acid. The methanogenesis fourth stage is the biochemical process where methane, carbon dioxide, and water are produced by methanogens.

A simplified overall chemical reaction for the degradation of sugars produced by the hydrolysis of cellulose is:

Thus, the desirable product of the landfill bioreactor is methane. Other products may (depending upon the composition of the waste material in the landfill) include (i) a solid fibrous material, which is spread without further treatment, or after post composting (maturation), to provide organic matter for improvement of soil quality and fertility (improves soil structure and reduces summer irrigation demand) and (ii) a liquid fraction which contains nutrients and can be spread as a fertilizer and sprayed on crops. If the solid and liquid fractions are not separated, the slurry can be spread on the soil.

Effective gas generation in bioreactors under saturated conditions of rapid differential settlement without a low permeable cover is impossible. The result of this practice, which significantly increases early gas generation without effective gas capture, is a significant near-term increase of potent greenhouse gas emissions into the atmosphere.

The use of clay caps and advanced liner systems and bentonite is useful for the prevention of leachate and landfill gas release, but a consequence of this is that moisture, which is required for the biodegradative processes, is often excluded. The result of this is that much of the waste can remain intact entombed inside the landfill, potentially for longer than the lifetime of the barriers. One method to reduce this effect, by enhancing and accelerating waste stabilization, is to operate the landfill as a bioreactor. The bioreactor landfill attempts to control, monitor, and optimize the waste stabilization process rather than contain the wastes as prescribed by most regulations. This is carried out in an aerobic environment as opposed to the normal situation in landfill sites, where conditions within the wastes are commonly anaerobic.

The future of the bioreactor may well be found in its use with an anaerobic system i.e., a hybrid arrangement. For example, air could be added to the anaerobic processes after the degradation of waste has occurred, thus removing excess moisture from the landfill and fully composting the waste. The cycling of both conditions (aerobic and anaerobic) also offers the possibility of treating a greater range of chemicals such as the nitrification and denitrification of ammonia.

See also: Anaerobic Digestion, Landfill Gas.

Biorefinery

A biorefinery is the means by which biomass can be converted to other products using a biochemical platform or a thermochemical platform which can be simply represented (Table B-29). Thus:

Table B-29 Simplified representation of a biorefinery.

Feedstock	Platform	Intermediate feedstock	Products
Biomass			
	Biochemical		
		Sugars	
			Fuels
			Chemicals
		Residues	
			Heat
			Power
	Thermochemical		
		Gas	
			Heat
			Power
			Fuels
			Chemicals
		Liquids	
			Fuels
			Chemicals

In the current context, the other products are biofuels which have the potential to replace certain crude oil-derived fuels. Thus, biorefining offers a key method to accessing the integrated production of chemicals, materials, and fuels. The biorefinery concept is analogous to that of an oil refinery except that biomass (instead of crude oil) is the feedstock to the refinery.

Biomass refers to (i) energy crops grown specifically to be used as fuel, such as fast-growing trees or switch grass, (ii) agricultural residues and by-products, such as straw, sugarcane fiber, and rice hulls, and (iii) residues from forestry, construction, and other wood-processing industries. These products can range from biomaterials to fuels such as ethanol or important feedstocks for the production of chemicals and other materials.

Biomass is a renewable energy source, unlike the fossil fuel resources (natural gas, crude oil, and coal) and, like the fossil fuels, biomass is a form of stored solar energy but produced in lesser time than the fossil fuels. Thus, a biorefinery is a facility that integrates biomass conversion processes and equipment to produce fuels, power, and chemicals from biomass. The concept is based on the modern crude oil refinery concept, which produces multiple fuels and products from crude oil. Industrial biorefineries have been identified as the most promising route to the creation of a new domestic biobased industry.

Plants are effective chemical mini-factories or refineries insofar as they produce chemicals by specific pathways. The chemicals they produce are usually essential manufacture (called metabolites) which include sugars and amino acids that are essential for the growth of the plant, as well as more complex compounds.

In a manner similar to the crude oil refinery, a biorefinery would integrate a variety of conversion processes to produce multiple product streams such as motor fuels and other chemicals from biomass (Table B-30). In short, a biorefinery would combine the essential technologies to transform biological raw materials into a range of industrially useful intermediates. However, the type of biorefinery would have to be differentiated by the character of the feedstock.

Table B-30 Simplified representation of a biorefinery.

Feedstock	Process (primary)	Products (intermediates)	Process (final)	Products
Biomass	Gasification	Heat		
		Power generation		
	Gas cleaning	Hydrogen		
	Synthesis gas		Fischer-Tropsch	Fuels
	Pretreatment	Cellulose	Hydrolysis	Sugars
Cellulose*	Hydrolysis	Sugars	Fermentation	Ethanol
				Bioproducts
				Chemicals

*Processes for the conversion of lignocellulose and lignin would also be included.

For example, the crop biorefinery would use raw materials such as cereals or maize and the lignocellulose biorefinery would use raw material with high cellulose content, such as straw, wood, and paper waste.

In addition, a variety of methods and techniques can be employed to obtain different product portfolios of bulk chemicals, fuels, and materials. Biotechnology-based conversion processes can be used to ferment the biomass carbohydrate content into sugars that can then be further processed. As one example, the fermentation path to lactic acid shows promise as a route to bio-degradable plastics. An alternative is to employ thermochemical conversion processes which use pyrolysis or gasification of biomass to produce a hydrogen-rich synthesis gas which can be used in a wide range of chemical processes. Thus, a biorefinery is a facility that integrates biomass conversion processes and equipment to produce fuels, power, and chemicals from biomass. The biorefinery concept is analogous to the crude oil refinery, which produce multiple fuels and products from crude oil.

A biorefinery can have different options for the production of biofuels from wood and other biomass materials. There is the (i) bioconversion, (ii) thermal conversion, and (iii) thermochemical conversion. Each of these options has merits, but selection is dependent on the feedstock and the desired product slate.

By producing multiple products, a biorefinery can take advantage of the differences in biomass components and intermediates and maximize the value derived from the biomass feedstock. A biorefinery might, for example, produce one or several low-volume, but high-value, chemical products and a low-value, but high-volume, liquid transportation fuel, while generating electricity and processing heat for its own use and perhaps enough for the sale of electricity. The high-value products enhance profitability, the high-volume fuel helps meet national energy needs, and the power production reduces costs and avoids greenhouse-gas emissions.

As a feedstock, biomass can be converted by thermal or biological routes to a wide range of useful forms of energy including process heat, steam, electricity, as well as liquid fuels, chemicals, and synthesis gas. As a raw material, biomass is a nearly universal feedstock due to its versatility, domestic availability, and renewable character. At the same time, it also has its limitations. For example, the energy density of biomass is low compared to that of coal, liquid crude oil, or crude oil-derived fuels. The heat content of biomass, on a dry basis (7,000 to 9,000 Btu/lb) is at best comparable with that of a low-rank coal or lignite, and substantially (50 to 100%) lower than that of anthracite, most bituminous coals, and crude oil. Most biomass, as received, has a high burden of physically adsorbed moisture, up to 50% by weight. Thus, without substantial drying, the energy content of a biomass feed per unit mass is even less.

These inherent characteristics and limitations of biomass feedstocks have focused the development of efficient methods of chemically transforming and upgrading biomass feedstocks in a refinery. The refinery would be based on two “platforms” to promote different product slates.

The sugar-base involves the breakdown of biomass into raw component sugars using chemical and biological means. The raw fuels may then be upgraded to produce fuels and chemicals that are interchangeable with existing commodities such as transportation fuels, oils, and hydrogen.

Although a number of new bioprocesses have been commercialized, it is clear that economic and technical barriers still exist before the full potential of this area can be realized. One concept gaining considerable momentum is the biorefinery which could significantly reduce production costs of plant-based chemicals and facilitate their substitution into existing markets. This concept is analogous to that of a modern oil refinery in that the biorefinery is a highly integrated complex that will efficiently separate biomass raw materials into individual components and convert these into marketable products such as energy, fuels, and chemicals.

By analogy with crude oil, every element of the plant feedstock will be utilized including the low-value lignin components. However, the different compositional nature of the biomass feedstock, compared to crude oil, will require the application of a wider variety of processing tools in the biorefinery. Processing of the individual components will utilize conventional thermochemical operations and state-of-the-art bioprocessing techniques. The production of biofuels in the biorefinery complex will service existing high-volume markets, providing economy-of-scale benefits and large volumes of by-product streams at minimal cost for upgrading to valuable chemicals. A pertinent example of this is the glycerol by-product produced in biodiesel plants. Glycerol has high functionality and is a potential platform chemical for conversion into a range of higher value chemicals. The high volume product streams in a biorefinery need not necessarily be a fuel but could also be a large-volume chemical intermediate such as ethylene or lactic acid.

A key requirement for delivery of the biorefinery concept is the ability to develop a process technology that can economically access and convert the five and six membered ring sugars present in the cellulose and hemicellulose fractions of the lignocellulosic feedstock. Although engineering technology exists to effectively separate the sugar containing fractions from the lignocellulose, the enzyme technology to economically convert the five ring sugars to useful products requires further development.

The construction of both large biofuel and renewable chemical production facilities coupled with the pace at which bioscience is being both developed and applied demonstrates that the utilization of non-food crops will become more significant in the near term. The biorefinery concept provides a means to significantly reduce production costs such that a substantial substitution of petrochemicals by renewable chemicals becomes possible. However, significant technical challenges remain before the biorefinery concept can be realized.

Bio-SCOT Process

The Bio-SCOT process is a combination of the SCOT and Shell-Paques processes. This process can reduce the sulfur emissions from the sulfur recovery facilities to a low level thanks to the higher efficiency of the scrubber in the Shell-Paques technology.

The process eliminates the need to recycle hydrogen sulfide back to the inlet of the Claus unit. The hydrogen sulfide is converted to solid elemental sulfur in the form of a slurry, which can be melted and mixed with the sulphur from the Claus unit.

See also: Biodesulfurization, SCOT Process, Tail Gas Cleaning.

Bioscrubbing

Bioscrubber systems have been used for hydrogen sulfide removal from gas streams. The bioscrubber involves a two-stage process with an absorption tower and a bioreactor, in which the sulfide is oxidized to sulfur and/or sulfate. For example, the Shell-Paques THIOPAQ® process employs alkaline conditions to produce elemental sulfur. In the first step of this process, the hydrogen sulfide is absorbed into an alkaline solution by reaction with hydroxyl and bicarbonate ions. In the second step, the hydrosulfide is oxidized to elemental sulfur under oxygen-limiting conditions. Thus:

See also: Biofiltration, Bio-oxidation, Gas Cleaning – Biological Methods Gas Processing, Gas Treating.

Bitumen

The term bitumen (also, on occasion, referred to as native asphalt, and extra heavy oil) includes a wide variety of reddish-brown to black materials of semisolid, viscous to brittle character that can exist in nature with no mineral impurity or with mineral matter contents that exceed 50% by weight. Bitumen is frequently found filling pores and crevices of sandstone, limestone, or argillaceous sediments, in which case the organic and associated mineral matrix is known as rock asphalt.

Bitumen is a naturally-occurring material that is found in deposits where the permeability is low and passage of fluids through the deposit can only be achieved by prior application of fracturing techniques. Tar sand bitumen is a high-boiling material with little, if any, material boiling below 350°C (660°F), and the boiling range approximates the boiling range of an atmospheric residuum.

In order to define bitumen, extra heavy oil, heavy oil, and conventional crude oil, the use of a single physical parameter such as viscosity is not sufficient. Physical properties such as API gravity, elemental analysis, and composition fall short of giving an adequate definition. It is the properties of the bulk deposit and, most of all, the necessary recovery methods that form the basis of the definition of these materials. Only then is it possible to classify crude oil, heavy crude oil, extra heavy crude oil, and tar sand bitumen. For example, *tar sands* have been defined in the United States (FE-76-4) as:

...the several rock types that contain an extremely viscous hydrocarbon which is not recoverable in its natural state by conventional oil well production methods including currently used enhanced recovery techniques. The hydrocarbon-bearing rocks are variously known as bitumen-rocks oil, impregnated rocks, oil sands, and rock asphalt.

The recovery of the bitumen depends to a large degree on the composition and construction of the sands. Generally, the bitumen found in tar sand deposits is an extremely viscous material that is *immobile under reservoir conditions* and cannot be recovered through a well by the application of secondary or enhanced recovery techniques.

The expression *tar sand* is commonly used in the crude oil industry to describe sandstone reservoirs that are impregnated with a heavy, viscous black crude oil that cannot be retrieved through a well by conventional production techniques (FE-76-4, above). However, the term *tar sand* is actually a misnomer; more correctly, the name *tar* is usually applied to the heavy product remaining after the destructive distillation of coal or other organic matter. Thus, alternative names, such as *bituminous sand* or *oil sand*, are gradually finding usage, with the former name (bituminous sands) more technically correct. The term *oil sand* is also used in the same way as the term *tar sand*, and these terms are often used interchangeably.

On an international note, the bitumen in tar sand deposits represents a potentially large supply of energy. However, many of the reserves are available only with some difficulty and that optional refinery scenarios will be necessary for conversion of these materials to liquid products because of the substantial differences in character between conventional crude oil and tar sand bitumen.

Because of the diversity of available information and the continuing attempts to delineate the various world tar sand deposits, it is virtually impossible to present accurate numbers that reflect the extent of the reserves in terms of the barrel unit. Indeed, investigations into the extent of many of the world's deposits are continuing at such a rate that the numbers vary from one year to the next.

The term *bitumen*, as used in oil shale technology is the lower molecular weight soluble, organic component of oil shale. The amount of bitumen is low, usually on the order of 0.5 to 5% w/w of the total weight of the oil shale. Thus, oil shale organic matter can be characterized as two materials, kerogen and bitumen, the latter being benzene soluble. Bitumen is also the product produced by the high molecular weight material thermal decomposition of kerogen.

The yield of bitumen (extractable material) increases with (i) increasing extraction temperature, (ii) with increasing polarity of the extraction solvent, and (iii) with the chemical reactivity of the solvent. Moreover, bitumen is generally richer in hydrogen (H/C may be on the order of approximately 1.6 with a molecular weight of approximately 1,200) and nitrogen, while it is lower in the proportion of aromatic constituents (and consequently richer in aliphatic constituents) than the corresponding kerogen.

Although the thermal decomposition kinetics is complex, the thermal decomposition of the bitumen (either extracted or produced from the thermal decomposition of kerogen) is often simply described (like the thermal decomposition of kerogen) by a kinetic mechanism involving a first order mechanism which involves the production of *thermal bitumen*:

Black Liquor

Black liquor is the solution of lignin-residue and the pulping chemicals from the Kraft process which is used to extract lignin during the manufacture of paper. The black liquor is an aqueous solution of lignin residues, hemicellulose, and the inorganic chemicals used in the process and contains more than half of the energy content of the wood fed into the digester. Black liquor (Table B-19) is typically concentrated to 65 to 80% by multi-effect evaporators and burned in a recovery boiler to produce energy and recover the cooking chemicals.

The gasification of black liquor has the potential to achieve higher overall energy efficiency while generating an energy-rich synthesis gas. The synthesis gas can be burned in a gas turbine combined cycle system or converted through Fischer-Tropsch chemistry into chemicals or fuels such as methanol, dimethyl ether (DME), gasoline, or diesel.

See also: Dimethyl Ether, Fischer-Tropsch, Methanol.

Blended Fuels

Blended fuel usually refers to a mixture composed of automotive gasoline and another liquid, other than a minimal amount of a product such as carburetor detergent or oxidation inhibitor, which can be used as a fuel in a motor vehicle.

Typically, in the current sense of the term, a blended fuel is a mixture of traditional fuels (such as gasoline or diesel fuel) and alternative fuels (such as ethanol or biodiesel, respectively) in varying percentages. The lowest-percentage blends are being marketed and introduced to work with current technologies while paving the way for future integration. For example, B5 and B20 (diesel fuel blended with 5% or a 20%, respectively of a biofuel) can be pumped directly into the tank of any diesel-fueled vehicle. Ethanol is also blended (approximately 10% v/v) into much of the gasoline dispensed in many countries, especially in metropolitan areas, to reduce emissions.

The use of blended fuels is part of the transition to using more alternative fuels. Although the pure alcohol (methanol or ethanol) will burn independently, cold weather starting can be a problem. An engine has to be designed exclusively for a particular fuel to take advantage of all the characteristics of that fuel. Without the infrastructure in place to support pure alcohol fuels, flex-fuel vehicles (FFVs) have been designed to run on both alcohol and gasoline. The flex-fuel vehicles join the best characteristics of both methanol and gasoline (or ethanol and gasoline) and make it possible to utilize higher blend percentages such as E85 (ethanol) and M85 (methanol). Examples of blended fuels are presented below.

E10

E10 is a low-level blend composed of 10% ethanol and 90% gasoline that has been approved by the United States Environmental Protection Agency (EPA) for use in any conventional, gasoline-powered vehicle. The use of E10 was spurred by the Clean Air Act Amendment of 1990 (and subsequent laws), which mandated the sale of oxygenated fuels in areas with unhealthy levels of carbon monoxide. Currently, the E10 fuel is sold in every state.

E15

E15 is a low-level blend composed of 10.5 to 15% v/v ethanol and gasoline and is approved for use in newer light-duty conventional vehicles. Stations must adhere to several EPA requirements and regulations when selling E15.

E85

E85 (or flex fuel) is an ethanol-gasoline blend containing 51 to 83% v/v ethanol, depending on geography and season that qualifies as an alternative that can be used in flexible fuel vehicles (FFVs), which have an internal combustion engine and are designed to run on E85, gasoline, or any blend of gasoline and ethanol up to 83% v/v.

See also: Alcohol Blended Fuels, E85.

Blending

Blending is a process which, in the current context, mixes the constituents of the fuel in such a manner as to ensure that there is a homogeneous mixture of all of the ingredients. The process can be carried out numerous times within a fuel manufacturing process when new excipients need to be added to the blend. Fuels as produced at the end of the process are actually blends of different streams since no one unit can, for example, produce specification-grade gasoline or diesel fuel. Thus, blending is the final operation in fuel production.

Blending consists of mixing the products in various proportions to meet specifications such as vapor pressure, specific gravity, sulfur content, viscosity, octane number, cetane index, initial boiling point, and pour point. Blending can be carried out in-line or in batch blending tanks. Air emissions from blending are fugitive volatile organic compounds (VOCs) from blending tanks, valves, pumps, and mixing operations. During the blending process, not only the physical and chemical properties of each blending component have to be considered in order to produce the specification-grade fuel and ensure that instability or incompatibility do not occur.

In fact, the major refinery products produced by the product blending process are gasoline, jet fuels, heating oils, and diesel fuels. The objective of product blending is to allocate the available blending components in such a way as

to ensure all product demands and specifications are met at the least cost and to produce products which maximize overall profit. Gasoline blending is a refinery operation that blends different component streams into various grades of gasoline. Typical grades include 83 octane (blended later with an oxygenated fuel such as ethanol), regular 87 octane, and premium 92 octane. The Reid Vapor Pressure (RVP) is set depending on the average temperature of the location the gasoline will be used (cold temperatures require higher RVP than warmer climates). These two specifications are the most significant, and they are documented with each blend, to minimize the potential for octane giveaway.

Most refiners use computer-controlled in-line blending for blending gasoline and distillates. Inventories of blending stocks, together with cost and physical property data, are maintained in a database. Many of the properties of blend components are non-linear, such as octane number, so estimating final blend properties from the components can be quite complex. When a certain volume of a given quality product is specified, the computer uses linear programming models (LP's) to optimize the blending operations to select the blending components to produce the required volume of the specified product.

See also: Blended Fuels.

Blue Gas

Blue gas is a mixture of gases and consists predominantly of carbon monoxide and hydrogen formed by action of steam on hot coal or coke. The mixture has a tendency to burn with a blue flame, hence the name of the gas.

See also: Blue Water Gas, Carbureted Blue Gas.

Blue Water Gas

Blue water gas (sometimes referred to as blue gas) is produced in a similar manner to produce gas but allows the production of a higher heat content gas by intermittent blasting the incandescent bed with air and steam such that the overall heat balance is maintained. The products of the air blast contain the nitrogen which reduces heat content of the product gas.

The process follows the similar principles to the production of producer gas with the exception that the problem of nitrogen dilution is overcome. The feedstock bed is simultaneously blasted with air followed by steam – the air reaction is exothermic causing the bed to increase in temperature, and this is balanced by the endothermic reaction of the steam. The typical composition of the product gas is on the order of carbon dioxide 5% v/v, carbon monoxide 41% v/v, hydrogen 49%, v/v, methane 1% v/v, and nitrogen 4% v/v. If oxygen is used instead of air, the process can be continuous and coke is preferred to coal because coal can continue to devolatilize in the blow period thereby reducing process efficiency – there are also issues related to process efficiency that arise from the use of caking coal as the feedstock.

The blue water gas may be enriched by adding a carburetor in which heavy (high density, high-boiling) fuel oil is sprayed into a brick lined chamber during the blow period of the blue water gas plant with air. During the make period, the air is turned off and the oil is cracked into smaller hydrocarbon derivatives in the now-heated chamber. This produces a mixture of hydrocarbon derivatives (predominantly methane) which increases the heat content and enriches the gas product.

See also: Blue Gas.

Boiler Slag

Boiler slag is a by-product produced from a wet-bottom boiler, which is a special type of boiler designed to keep bottom ash in a molten state before it is removed. These types of boilers (slag-tap and cyclone boilers) are much more compact than pulverized coal boilers used by most large utility generating stations and can burn a wide range of fuels and generate a higher proportion of bottom ash than fly ash (50 to 80% w/w bottom ash compared to 15 to 20% w/w bottom ash for pulverized coal boilers). With wet-bottom boilers, the molten ash is withdrawn from the boiler and allowed to flow into quenching water. The rapid cooling of the slag causes it to immediately crystallize into

a black, dense, fine-grained glassy mass that fractures into angular particles, which can be crushed and screened to the appropriate sizes for several uses.

There are two types of wet-bottom boilers: (i) the slag-tap boiler and (ii) the cyclone boiler. The slag-tap boiler burns pulverized coal, and the cyclone boiler burns crushed coal. In each type, the bottom ash is kept in a molten state and tapped off as a liquid. Both boiler types have a solid base with an orifice that can be opened to permit the molten ash that has collected at the base to flow into the ash hopper below. The ash hopper in wet-bottom furnaces contains quenching water. When the molten slag comes in contact with the quenching water, it fractures instantly, crystallizes, and forms pellets. The resulting boiler slag, often referred to as *black beauty*, is a coarse, hard, black, angular, glassy material.

Since boiler slag is angular, dense, and hard, it is often used as a wear-resistant component in surface coatings of asphalt in road paving. Finer-sized boiler slag can be used as blasting grit and is commonly used for coating roofing shingles. Other uses include raw material for the manufacture of cement and in colder climates; it is spread onto icy roads for traction control. Because there are so many uses and such a limited supply, most of the boiler slag produced in the United States is used and some even imported from other countries.

Boiling Water Reactor

A boiling water reactor (BWR) is a type of light (H_2O and not HDO or D_2O in which hydrogen has been replaced by deuterium) water nuclear reactor used for the generation of electrical power.

The steam in boiling water reactor is produced directly in the reactor core, while, in contact, the steam in a pressurized water reactor (PWR) is produced in a secondary system. The pressure of a pressurized boiling reactor varies from the primary system to the output steam, while the pressure of a boiling water reactor remains constant.

An advantage of the pressurized water reactor is that the pressurized water reactor can operate at higher temperature and pressure on the order of approximately 315°C (600°F) and 2,400 psi. This provides a higher efficiency than the boiling water reactor.

See: Nuclear Reactor – Boiling Water Reactor.

Bone Dry

The term bone dry when applied to biomass or a biomass product refers to 0% moisture content and refers to (in this context) the biomass being extremely or completely dry. For example, wood heated in an oven at a constant temperature of 100°C (212°F) or above until its weight stabilizes is considered bone dry or oven dry.

Boson

A boson is a particle which carries a force and has a whole number spin (spin is a property of subatomic particles). Bosons carry energy. A photon is an example of a boson as it has a spin of 1 and carries electromagnetism. Mesons are also bosons as they carry nuclear force.

See also: Electron, Nuclear Energy, Photon, Positron.

Bottom Ash

The most common type of furnace in the electric utility industry is the dry, bottom- pulverized feedstock boiler. When pulverized feedstock is burned in a dry, bottom boiler, approximately 80% w/w of the unburned material or ash is entrained in the flue gas and is captured and recovered as fly ash. The remaining 20% w/w of the ash is dry bottom ash, a dark gray, granular, porous solid that is collected in a water-filled hopper at the bottom of the furnace.

When a sufficient amount of bottom ash drops into the hopper, it is removed by means of high-pressure water jets and conveyed by sluiceways, either to a disposal pond or to a decant basin for dewatering, crushing, and stockpiling for disposal or use.

Bottom ash is the coarser component of the ash and may comprise a substantial portion of the waste. Rather than floating into the exhaust stacks, it settles to the bottom of the power plant boiler. Bottom ash is not quite as useful as fly ash, although power plant owners have tried to develop options for beneficial use options, such as structural fill and road-base material. However, the bottom ash remains toxic when recycled and can leak heavy metals into the groundwater.

See also: Ash, Biomass Ash, Boiler Slag, Fly Ash.

Bottoming Cycle

The bottoming cycle is a cogeneration system in which steam is used first for process heat and then for electric power production. In the plant, a waste-heat recovery boiler recaptures the unused energy and uses it to produce steam to drive a steam turbine generator to produce electricity.

Bottoming cycle plants produce high temperature heat for industrial processes, and then a waste heat recovery boiler feeds an electrical plant. These plants are only used when the industrial process requires high temperatures, such as furnaces for glass and metal manufacturing, so they are less common.

Bottom Sediment and Water

Bottom sediment and water (sometimes referred to as basic sediment and water, BS&W) is a both a technical specification of certain impurities in liquid feedstocks and fuels and the method for measuring these properties. In the crude state, many fuels contain water and suspended solids – the particulate matter is also referred to as sediment. The water and solids are measured as BS&W. Considerable importance is attached to the presence of water or sediment in fuels because the water and sediment lead to difficulties in use.

Water, with its dissolved salts, may occur as easily removable suspended droplets or as an emulsion. The sediment dispersed in crude oil may be comprised of inorganic minerals from the production of the fuel as well as scale and rust from pipelines and tanks used for oil transportation and storage. Usually, water is present in far greater amounts than sediment but, collectively, it is unusual for them to exceed 1% of the crude oil on a delivered basis. Water and sediment can foul heaters, stills, and exchangers and can contribute to corrosion and to deleterious product quality. Also, water and sediment are principal components of the sludge that accumulates in storage tanks and must be disposed of periodically in an environmentally acceptable manner. Knowledge of the water and sediment content is also important in accurately determining net volumes of crude oil in sales, taxation, exchanges, and custody transfers.

The sediment consists of finely divided solids that may be drilling mud or sand or scale picked up during the transport of the fuel. The solids may be dispersed in the fuel or carried in water droplets. In any form, water and sediment are highly undesirable in a fuel and the relevant tests involving distillation (ASTM D95, ASTM D4006), centrifuging (ASTM D4007), extraction (ASTM D473), and the Karl Fischer titration (ASTM D4377, ASTM D4928) are regarded as important in fuel quality examinations.

Boudouard Reaction

The Boudouard reaction is a gasification reaction in which the carbon dioxide formed reacts with carbon to form carbon monoxide:

The reaction is an endothermic reaction and is favored at high temperatures (680°C, 1255°F). Unlike the gasification reactions, combustion reactions are highly exothermic, so the heat generated in combustion is usually balanced by the steam gasification reaction to attain heat integration. An idealized char gasifier with all inlet and outlet streams is used at the same temperature (i.e., 370°C, 700°F).

Breeder Reactor

A breeder reactor is a type of nuclear reactor which produces more fissile materials than they consume. The reactor is designed to extend the nuclear fuel supply for the generation of electricity, and has even been mistakenly called a potential renewable energy source.

By irradiation of a fissile material such as uranium-238 (^{238}U) or thorium-232 (^{232}Th), the reactor creates more fissile material than is used. Breeder reactors were at first found viable because they made more complete use of uranium fuel than light water reactor. Typically, a breeder reactor creates 30% more fuel than it consumes. After an initial introduction of enriched uranium, the reactor only needs infrequent addition of stable uranium, which is then converted into the fuel.

See: Nuclear Reactor – Breeder Reactor.

BRI Process

The BRI process uses a two-stage gasifier that raises the syngas temperature as high as 1,370 °C (2,500 °F) in the second stage to enable cracking of any high-boiling hydrocarbon derivatives to carbon monoxide and hydrogen, maximizing the ethanol yield, thus using a thermal cracking.

The hot producer gases are cooled to 37°C (98°F), and introduced into the biocatalytic reactor where ethanol is produced. Here, the modified bacteria culture *Clostridium ljungdahlii* is introduced and nutrients are added to provide for cell growth and automatic regeneration of the biocatalyst.

With a hydrogen/carbon monoxide ratio of 2, the reactions indicate that water and ethanol are the only products.

As the ethanol is toxic to the bacteria, there is a need to hold the ethanol concentrations below 3% in the reactor. A dilute, aqueous stream of ethanol is continuously removed through a membrane that retains cells for recycle to maximize reaction rates. Anhydrous ethanol is produced by conventional distillation followed by a molecular sieve, using the waste heat from the process. Water, with nutrients, is recycled from the distillation bottoms back to the biocatalytic reactor. With ambient temperature and pressures, a fermentation time of a few minutes has been achieved.

Briquette

A briquette (or briquet) is a block of carbonaceous smokeless fuel (flammable matter) which is used as fuel to start and maintain a fire. Common types of briquettes are charcoal briquettes and biomass briquettes. Briquettes are used for both domestic and industrial use, prepared from bituminous coal using a binder. Briquette production is a mature technology, and the technology associated with coal briquetting has been developed for almost 100 years.

Historically, briquettes (especially coal and coke briquettes) have been used for fuel for approximately 100 years. Traditionally, briquetting technology was established for developing countries to produce briquettes of local residues, for use in household cooking stoves and restaurants. Later, as the capacities of the machines increased, briquettes were used in industrial boilers to create heat, steam, and power for industry and power plants. Within the past three decades, briquetting has also found its way to households in industrialized countries as consumer logs for wood-burning stoves and fireplaces. However, with the advent of modern fuel systems, the use of briquettes has declined and use for these products is found most often in the operation of barbecue units. While still a marketable product for such use, briquettes as fuel (such as *smokeless fuel*) are not used often for domestic and industrial heating. In more recent years, as the focus on renewable energy has grown, the applications for briquettes have grown concurrently, as have different technologies and new applications.

The briquette has to be ignited from the bottom by burning wood. During ignition, the upper part of briquette, upon heating, emits volatile matter which is a mixture of carbon and hydrogen compounds and is a strong pollutant. The newly developed briquettes can be ignited from the top just by striking a match, and the volatile matter will be burnt away when it has passed the upper flame. The briquette should be coated with a thin layer of combustibles and oxidizing agent and, therefore, should be kept in a dry place lest moisture retards ignition.

See also: Briquette Binder, Briquette Manufacture.

Briquette Binder

The binder used for coal briquetting has considerable influence of the properties of the finished product. Coke-oven tar (or the solid pitch) has been, and continues to be, widely used as a binder in the production of briquettes from bituminous coal, although crude oil-derived products are also being used.

The composition of bituminous coal tar and pitch is complex and consists of a wide variety of components. The coke-forming components of the pitch are of great importance for briquetting, and pitch from low-volatile coal (such as anthracite) has been preferred. These coals do not cake or melt while burning in the furnace; thus, the stability of the briquettes depends entirely on the skeleton of pitch coke formed in the briquette structure. Furthermore, the content of coke-forming components in the tar pitch increases as the rate of pitch distillation is decreased.

Pitch viscosity also exerts a strong influence on the process as do the coal-binder interactions. During the briquetting process, the properties of the binder pitch are changed by heat, duration of the process, air, and steam. These factors can change pitch composition in the thin layer present in the heated briquetting matrix.

Crude oil residua used in the briquetting of coals have often been given the collective name asphalt (*bitumen* in Europe and many other countries). The most important data used to characterize such asphalt is the softening point, the penetration, the Conradson carbon residue, and the plasticity range which indicate the thermoplastic character of the binder and content of coke-forming components.

These two properties are considerably different in asphalt and coal-tar pitch. Crude oil-derived materials have a lower content of coke-forming components than coal-tar pitch, and this may be a disadvantage when crude oil-derived materials are used as binders for noncaking coal briquettes. Use of crude oil-derived materials having a lower than-desirable propensity for coke formation, as indicated by a low Conradson carbon residue, produces briquettes that have a low stability during firing.

Propane asphalt (produced in a crude oil refinery) has a lower penetration value than asphalts obtained by distillation or by oxidation. Propane asphalt has a relatively high temperature sensitivity which may cause the briquettes to adhere more efficiently. It is possible to alter the temperature sensitivity of the propane asphalt by the conventional methods of treatment which are used to alter asphalt properties for highway use.

Sulfite liquor is a by-product obtained during the treatment of wood with sulfites (calcium, sodium, magnesium, and ammonium) to produce cellulose. The liquor has significant adhesion properties thereby fulfilling one of the binder requirements for use as a briquette binder.

The sulfite liquor and the sulfite pitch remaining after water removal are water soluble. Briquettes made with sulfite liquor as the binder can be rendered water-resistant (referred to as *hardening the briquette*) by heating to 220 to 350°C (430 to 660°F).

Slightly sintering or lightly caking coals can be briquetted with calcium sulfite liquor or with magnesium or sodium sulfite liquor as a binder. Briquettes that are stable during firing can be made from anthracite coals only when using ammonium sulfite liquor. This low-ash binder produces a favorable coke skeleton in the briquette structure during combustion.

Starch has a substantial adhesive power, and 1 to 3% w/w starch added to the coal, as a solid or in a suspension, can be used as a binder for the production of coal briquettes. Starch is used in the manufacture of charcoal briquettes, which are used in increasing amounts as barbeque briquettes.

See also: Briquette, Briquette Manufacture.

Briquette Manufacture

Briquette manufacture (also known as briquetting) is undergoing resurgence, principally due to the convergence of three critical factors. In fact, the recent developments in briquette processing and binding have dramatically changed the economics of using fuel briquettes as an energy resource. Also, a shortage of fuel wood has become increasingly severe in most of the developing countries. Finally, there has been a steady increase by environmental concerns to address the problem of domestic and urban waste disposal, a dilemma that briquetting can help remedy.

Generally, briquette manufacture (briquetting) involves the collection of combustible materials that are not usable as such because of their low density, and compressing them into a solid fuel product of any convenient shape that can be burned like wood or charcoal. Thus, the material is compressed to form a product of higher bulk density, lower moisture content, and uniform size, shape, and material properties. Briquettes are easier to package and store, cheaper to transport, more convenient to use, and their burning characteristics are better than those of the original organic waste material.

The raw material of a briquette must bind during compression; otherwise, when the briquette is removed from the mold, it will crumble. Improved cohesion can be obtained with a binder but also without, since under high temperature and pressure, some materials such as wood bind naturally. A binder must not cause smoke or gummy deposits, while the creation of excess dust must also be avoided. Two different sorts of binders may be employed. Combustible binders are prepared from natural or synthetic resins, animal manure or treated, dewatered sewage sludge. Non-combustible binders include clay, cement, and other adhesive minerals. Although combustible binders are preferable, non-combustible binders may be suitable if used in sufficiently low concentrations. For example, if organic waste is mixed with too much clay, the briquettes will not easily ignite or burn uniformly. Suitable binders include starch (5 to 10%) or molasses (15 to 25%), although their use can prove expensive. It is important to identify additional, inexpensive materials to serve as briquette binders and the optimum concentrations of the materials. The exact method of preparation depends upon the material being briquetted but, in general, the overall process can be presented as a step-wise operation: Thus:

Collection

Drying

Size reduction

Binder addition

Briquetting

Drying

Sales

See also: Briquette, Briquette Binder, Briquette Properties, Briquetting Processes.

Briquette Properties

The shape and the size of briquettes depend essentially on their application. Briquettes for industrial use are usually cubes or bricks weighing 1 to 4 lbs. The briquettes manufactured for domestic use must be small enough to be loaded conveniently through the appliance filling aperture but not small enough to drop through the grate bars or to give high resistance to air flow, even in deep beds.

There are few, if any, recognized specifications or standard tests available for measuring the mechanical properties of bituminous coal briquettes. The properties currently measured are the breaking strengths and the abrasion or attrition of the briquettes. The attrition testing of briquettes by means of the tumbler tests permits the comparison of briquettes that have the same weight but different shapes (breaking or crushing strengths of briquettes that vary in shape cannot be compared). The test involves placing the briquette between two parallel plates and loading one plate until the briquette breaks. The larger the surface of contact between the testing plate and the briquette, the larger the point compressive strength.

The thermal post-treatment of the briquettes at different temperatures, with or without the influence of oxygen in the air, leads to briquettes which (depending on the feed material, the treatment method, and the treatment temperature) have properties more or less similar to those of coke. The briquettes undergo carbonization in one of several steps. The thermal post-treatment depends on the type of briquettes being treated and the desired properties of the final product. Heating rate and residence time in the hot zone are the deciding factors; however, the composition properties of the raw briquettes also influence the processing steps and the nature of the final product.

If the binder pitch softens, the briquettes may be deformed, or glued together as a result of the exuding of binder from the briquette surface. Such difficulties are avoided by an oxidative hardening pretreatment or by maintaining the briquettes in a quiescent state during the temperature interval used for binder softening.

The most important data used to characterize briquette binders are the softening point, the penetration, the carbon residue, and the plasticity range. These data indicate the thermoplastic behavior of the binder and content of coke-forming components. These two properties are considerably different in bitumens and coal-tar pitches. For example, crude oil-derived materials have a lower content of coke-forming components than coal-tar pitch, and this may be a disadvantage when crude oil-derived materials are used as binders for noncaking coal briquettes, especially of anthracites. Use of crude oil-derived materials having a lower-than-desirable propensity for coke formation, as indicated by a low Conradson carbon residue, produces briquettes that have a low stability during firing.

The use of propane asphalt as a briquette binder has also been investigated; propane asphalt is the propane-insoluble portion of crude oil residua. The asphalt has a lower penetration value than asphalts obtained by distillation or by oxidation. Propane asphalt has a relatively high temperature sensitivity which may cause the briquettes to stick together. It is possible to alter the temperature sensitivity of the propane asphalt by the conventional methods of treatment which are used to alter asphalt properties for highway use.

Briquetting Processes

The processes available for the production of briquettes are many and, often, not too varied. The production of coal briquettes is closely related to the carbonization process by which fuel-grade coke is produced. In fact, briquettes are manufactured from coals that are normally considered to be of insufficient quality to produce coke. A non-caking coal having a low content of volatile matter might be briquetted with a binder at 750 to 800°C (1,380 to 1,470°F).

A recent emphasis on the use of coal is the production of added-value products using a variety of processes by which the total coal can be used with little wastage of the products. Such is the character of the mild gasification process and a variety of other clean coal processes which have brought related to renewed interest in briquetting and pelletization of coal.

The mild gasification process is a modification of the conventional coal gasification and produces gaseous, liquid, and solid products by heating coal in an oxygen-free reactor. The process is less of a gasification process and more of a pyrolysis process insofar as volatile matter is removed by thermal means to leave a carbonaceous char/residue. The char can be upgraded further to remove both ash and pyritic sulfur, mixed back with coal-derived liquids, and burned in both coal- and oil-fired boilers.

The process is of interest since a slurry of the liquid fuel and the upgraded char has the potential of being a very versatile fuel that can be burned in both coal- and oil-fired boilers. If the char is upgraded to a high degree, even feedstock coal with a high sulfur content can be used without alternating heat rates or capacity factors.

The production of briquettes (and/or pellets) from coal is a thermal decomposition process, akin to the carbonization process.

Carbonization is essentially a thermal treatment process for the production of a carbonaceous residue (with the simultaneous removal of distillate) from a variety of organic substances:

The process may also be referred to as destructive distillation and has been applied to a range of organic materials, but more particularly to naturally-occurring materials such as wood, sugar, and vegetable matter. The carbonaceous residue from the thermal decomposition of coal is usually referred to as coke (which is physically dissimilar from charcoal) and has the more familiar honeycomb-type structure.

The thermal decomposition of the carbonaceous feedstock is a complex sequence of events which can be described in terms of several important physicochemical changes, such as the tendency of the feedstock to soften and flow when heated or the relationship to carbon-type in the feedstock. In fact, some feedstocks become quite fluid at temperatures of the order of 400 to 500°C (750 to 930°F) and there is a considerable variation in the degree of maximum plasticity, the temperature of maximum plasticity, as well as the plasticity temperature range for some feedstocks. Significant changes also occur in the structure of the char during the various stages of devolatilization.

A briquetting plant typically consists of the mixer-dryer with drive, the fan, and the gas ducts. From the mixing chamber, flue gas at 300 to 500°C (570 to 930°F) passes through the coal-binder mixture, suction being provided by the fan. After cooling, the material enters roll presses from the mixer-dryer.

Water, among other factors, influences the wetting and adhesion between coal and bituminous binder and on the strength of the resultant briquette. Indeed, interfacial interactions between the coal and the binder are extremely important in determining the strength of the briquette. The moisture content of the feedstock, before the addition of the bituminous binder, should be as low as possible, preferably not exceeding 4% w/w.

Bromine Number

The bromine number is used as a method of determining the unsaturation in typical hydrocarbon molecules.

The bromine number is the number of grams of bromine absorbed by 100 g of oil which indicates the percentage of double bonds in the material. The number is an indicator of the unsaturated constituents in a liquid fuel. In the test method, a known weight of the sample dissolved in a specified solvent maintained at 0 to 5°C (32 to 41°F) is titrated with standard bromide-bromate solution. However, the determination of the end point is method dependent.

BTEX

BTEX is an acronym that stands for benzene, toluene, ethylbenzene, and xylenes that occur in the lower-boiling liquid fuels (Figure B-3). These compounds are some of the volatile organic compounds (VOCs) found in crude oil derivatives such as gasoline.

Figure B-3 Constituents of the BTEX Mixture.

Toluene, ethylbenzene, and xylenes have harmful effects on the central nervous system. BTEX compounds are notorious due to the contamination of soil and groundwater, which typically occurs near crude oil and natural gas production sites, and petrol stations and other areas with underground storage tanks (USTs) or above-ground storage tanks (ASTs) containing gasoline or other crude oil-related products.

The analysis for the BTEX group is performed using a purge and trap device which, owing to differences in volatility and water insolubility, easily separates the BTEX group from the complex sample matrix. In addition, the analytes are identified with a photo-ionization detector (PID) which responds selectively to aromatic hydrocarbon derivatives while showing only a small or negative response to paraffin derivatives, oxygenated hydrocarbon derivatives, and other components of the gas stream. Hence, the BTEX analysis is not only one of the most commonly requested, but also a fairly simple, straightforward method.

See also: BTX.

BTU

The Btu (British thermal unit) is a unit of measurement for energy and is the amount of heat that is necessary to raise the temperature of one pound of water by 1 degree, Fahrenheit.

BTX

BTX is an acronym for benzene, toluene, and xylene, which are components of the lower-boiling liquid fuels.

Benzene, the simplest aromatic, is carcinogenic, and its level in gasoline is severely restricted. Toluene and xylene have benzene rings which are attached to one or two methyl (CH_3) groups, respectively; xylene has three isomers, with the methyl groups adjacent on the ring (ortho), separated by one carbon (meta), or separated by two carbons (para):

See also: BTEX.

Bubble Point

The bubble point is the temperature at which incipient vaporization of a liquid in a liquid mixture occurs, corresponding with the equilibrium point of 0% vaporization or 100% condensation. The bubble point is based on the fact that liquid is held in the pores of the filter by surface tension and capillary forces. The minimum pressure required to force liquid out of the pores is a measure of the pore diameter. The pressure required to force liquid out of a liquid-filled capillary must be sufficient to overcome surface tension and is a direct measure of an effective tube diameter.

The *bubble point pressure* (P_b) is the pressure at which saturation will occur in the liquid phase (for a given temperature) and is the point at which vapor (bubble) first starts to come out of the liquid (due to pressure depletion). The bubble point temperature is usually lower than the dew point temperature for a given mixture at a given pressure.

Since the vapor above a liquid will probably have a different composition to the liquid, the bubble point (along with the *dew point*) data at different compositions are useful data when designing distillation systems and for constructing phase diagrams as a means of studying phase relationships. As pressures are reduced below the bubble point, the relative volume of the gas phase increases. For pressures above the bubble point, a crude oil is said to be undersaturated. At or below the bubble point, the crude is saturated.

A bubble point test is a test method that is designed to determine the pressure at which a continuous stream of bubbles is initially seen downstream of a wetted filter under gas pressure. The bubble point test is a practical,

nondestructive test used for estimating the pore size of microporous filters and confirming the integrity of sterilizing membrane filters and filter systems. It is the most widely used non-destructive integrity test.

To perform a *bubble point test*, gas is applied to one side of a wetted filter, with the tubing downstream of the filter submerged in a bucket of water. The filter must be wetted uniformly such that water fills all the voids within the filter media. When gas pressure is applied to one side of the membrane, the test gas will dissolve into the water, to an extent determined by the solubility of the gas in water. Downstream of the filter, the pressure is lower. Therefore, the gas in the water on the downstream side is driven out of solution. As the applied upstream gas pressure is increased, the diffusive flow downstream increases proportionally. At some point, the pressure becomes great enough to expel the water from one or more passageways establishing a path for the bulk flow of air. As a result, a steady stream of bubbles should be seen exiting the submerged tubing. The pressure at which this steady stream is noticed is referred to as the bubble point.

Bubbling Fluidized Bed Gasifier

A bubbling fluidized bed (BFB) consists of fine, inert particles of sand or alumina, which are selected based on their suitability of physical properties such as size, density, and thermal characteristics. The gas flow rate is chosen to maintain the bed in a fluidization condition, which enters at the bottom of the vessel.

The dimension of the bed at some height above the distributor plate is increased to reduce the superficial gas velocity below the fluidization velocity to maintain inventory of solids and to act as a disengaging zone. A cyclone is used to trap the smaller size particle that exit the fluidized bed, either to return fines to the bed or to remove ash rich fines from the system.

Biomass is introduced either through a feed chute to the top of the bed or deep inside the bed. The deeper introduction of biomass in to the bed of inert solids provides sufficient residence time for fines that would otherwise be entrained in the fluidizing gas. The biomass organics pyrolytically vaporize and are partially combusted in the bed. The exothermic combustion provides the heat to maintain the bed at temperature and to volatilize additional biomass.

The bed needs to be preheated to the startup temperature using hydrocarbon resources such as natural gas, fuel oil, either by direct firing or by indirect heating. After the bed reaches the biomass ignition temperature, biomass is slowly introduced into the bed to raise the bed temperature to the desired operating temperature which is normally in the range of 700 to 900°C (1,290 to 1,650°F). Bed temperature is governed by the desire to obtain complete devolatilization versus the need to maintain the bed temperature below the biomass ash fusion temperature. The advantages of the fluidized bed gasifiers are (i) yield of a uniform product gas, (ii) able to accept wide range of fuel particles sizes, including fines, (iii) a near-uniform temperature distribution throughout the reactor, and (iv) a high rate of heat transfer between inert material and biomass, aiding high conversion, with low tar. The disadvantage is formation of large bubbles at higher gas velocities, which bypass the bed reducing the high rate of heat /mass transfer significantly.

See also: Biomass – Gasification.

Bulk Density

The bulk density is the mass of an assembly of coal particles in a container divided by the volume of the container, assuming that the container is full and represents the volume occupied by the solid. The bulk density depends on true density, particle size and size distribution, particle shape, surface moisture, and degree of compaction. The parameter is often used in the design of coal handling, transportation, and storage systems.

Bulk density is a property of powders, granules, and other “divided” solids, especially used in reference to coal and similar solids. The total volume includes particle volume, inter-particle void volume, and internal pore volume.

The bulk density is not an intrinsic property of a material; it can change depending on how the material is handled. For example, powdered coal poured into a cylinder will have a particular bulk density, but if the cylinder is disturbed, the coal particles will move and usually settle closer together, resulting in a higher bulk density. For this

reason, the bulk density of powders is usually reported both as freely settled and tapped density – the tapped density refers to the bulk density of the coal powder after a specified compaction process, usually involving vibration of the container.

The test method (ASTM D291) for determining bulk density concerns the compaction of crushed coal to determine either its compacted or uncompacted weight, for purposes such as charging coke ovens. In addition to the character of the coal itself, moisture content and size distribution of the coal are the two main factors that affect the cubic foot weight. A moisture determination and sieve analysis of the coal should be reported along with the cubic foot weight for proper interpretation of the cubic foot weight. During the period of collecting the gross sample, the increments of the sample shall be stored in a waterproof container with a tightly fitting cover in order to prevent the loss of moisture.

The bulk density differs widely between different types of biomass. Together with the heating value, it determines the energy density of the gasifier feedstock, i.e., the potential energy available per unit volume of the feedstock. Biomass of low bulk density is expensive to handle, transport, and store. Apart from handling and storing behavior, the bulk density is important for the performance of the biomass as a fuel inside the reactor: a high void space tends to result in channeling, bridging, incomplete conversion and a decrease in the capacity of the gasifier. The bulk density varies widely (100 to 1,000 kg/m³) between different biomass feedstocks not only because of the character of the biomass but also as a result of the way the biomass comes available (chips, loose, baled).

Bunker

A bunker is a storage tank used for gaseous fuels, liquid fuels, and biomass fuel products.

Fuel bunkers, commonly known as bunkers, are containers for the storage of fuel on steam-powered boats or steam tank engines or rooms for the storage of fuel in furnaces. The term bunker or fuel bunker is typically only used for storage areas for solid fuels (such as coal or, in the current context, solid biofuel). The term fuel tank is typically used for liquid fuels) or gaseous fuels.

Bunker Fuel Oil

Bunker fuel is technically any type of fuel oil used aboard ships. It gets its name from the containers on ships and in ports that it is stored in; in the days of steam, they were coal bunkers, but now, they are bunker-fuel tanks.

Bunker fuel is the colloquial term for fuel oil used by marine vessels. Bunker fuels A, B, and C are respectively downgrading quality-classifications of fuel oil, characterized by their boiling points, carbon-chain lengths, and viscosities, all of which contribute to their value (in other words, Bunker A is more valuable than Bunker C). Currently, most of the global shipping fleet relies on diesel Bunker C fuel oil which contributes significant amounts of greenhouse gas emissions, sulfur, and other emissions that contribute negatively to climate change and negative environmental and human health impacts.

More specifically, bunker A is No. 2 fuel oil, bunker B is No. 4 or No. 5, and bunker C is No. 6. Since No. 6 is the most common, bunker fuel is often used as a synonym for No. 6. No. 5 fuel oil is also called navy special fuel oil or just navy special, No. 6 or 5 are also called furnace fuel oil (FFO); the high viscosity requires heating, usually by a recirculated low pressure steam system, before the oil can be pumped from a bunker tank. In the context of shipping, the labeling of bunkers as previously described is rarely used in modern practice.

Butane

Butane is a gaseous component of natural gas. Butane can also be produced from crude oil. Butane gas (n-butane) is the four-carbon unbranched alkane (CH₃CH₂CH₂CH₃). Butane is also used as a collective term for n-butane together with its only other isomer, iso-butane [methylpropane, CH(CH₃)₃]. Butanes are highly flammable, colorless, odorless, easily liquefied gases.

Butane is sold bottled as a fuel for cooking and camping. When blended with propane and limited amounts of other hydrocarbon derivatives (subject to the specifications), it is referred to commercially as liquefied petroleum gas. It is also used as a gasoline component and as a feedstock for the production of base petrochemicals in steam cracking, as well as a propellant in aerosol sprays.

Very pure forms of butane, especially iso-butane, can be used as refrigerants and have largely replaced the ozone layer-depleting halomethanes in household refrigerators and freezers. The flammability of butane is not usually an issue because the amount of butane in an appliance is not enough to cause a combustible mix given the amount of air in a room.

Butane Dehydrogenation

The *butane dehydrogenation process* is a process for removing hydrogen from butane to produce butenes and, on occasion, butadiene.

This process is achieved in several ways – the most common method is to heat hydrocarbon derivatives to high temperature, as in thermal cracking, that causes some dehydrogenation. In the chemical process industries, nickel, cobalt, platinum, palladium, and mixtures containing potassium, chromium, copper, aluminum, and other metals are used in very large-scale dehydrogenation processes.

n-Butane, iso-butane, and t-butane, while naturally occurring, have few commercial applications beyond fuels. Butanes can be isomerized and then reacted with iso-butene or other light olefins in alkylation processes to yield high-octane motor gasoline blending stock. Butenes, 1-butene, cis-2-butene, trans-2-butene, and iso-butene, also known as butylenes, by comparison have a variety of commercial uses. Iso-butene is a primary reactant in the production of methyl tertiary butyl ether (MTBE), a major additive in reformulated gasoline and used to reduce emissions from automobile exhaust. Butenes are oligomerized and hydrogenated to produce higher alkanes for gasoline blend stock uses and can be reacted further to produce other commercially important products. It is estimated that 90% of butene consumption is in motor fuel applications such as alkylate, polymer gasoline, and oligomerized gasoline blend stocks. Butenes are also blended directly into gasoline and mixed with propane and butanes in liquefied petroleum gas. Approximately 10% of the available butenes are used in chemical production where the most important products are butadiene, sec-butyl alcohol, butyl rubber, and polybutylene elastomer.

Butenes are produced as by-products of many refinery processes. Due to the huge volumes of crude oil subjected to catalytic cracking, catalytic crackers are the single largest source of mixed butenes that are typically used for MTBE production. Cracking catalysts and conditions are sometimes formulated and selected to especially maximize the production of iso-butene. Steam cracking of olefins is another major source of by-product butenes.

Butenes are dehydrogenated further to produce butadiene. Butadiene is one of three copolymers in abs, acrylonitrile-butadiene-styrene plastic and styrene-butadiene rubber. Dehydrogenation reactions are endothermic, and those of butane and butene are no exception.

One goal of the various processes for producing either butenes or butadiene is to maximize feedstock conversion and simultaneously selectivity to the desired product isomer. For example, while mixed butenes are typically used for MTBE and polygas synthesis, polybutylene production requires higher purity 1-butene. The yield of each isomer is controlled by the reaction conditions employed. The recovered yield is controlled by the downstream separation steps applied to the mixture of product and un-reacted starting materials. The practical result of these sometimes conflicting demands is a wide range of conversion technologies and separation approaches, each more or less optimized for a specific end use application.

Maximization of the conversion of feed to product can be accomplished by reducing the vapor pressure of the products in the reactor. A common practice is to add steam to the reactor. This not only reduces the partial pressure of the products driving the conversion higher; it is typically also utilized to import the needed heat of reaction into the reaction vessel. Steam is used because it can be easily separated from the reactor effluent through condensation. Another approach is to selectively remove one of the products of the reaction from the reactor, in this case the hydrogen.

Hydrogen is removed by oxidation to produce water and also to supply some of the required heat of reaction. The direct addition of small amounts of oxygen into the reactor, typically in a specially designed reaction zone, usually with a catalyst present has been described. The risk with this solution is the indiscriminate reaction of the oxygen with either the reactants or the products.

Another approach is to control the side reactions of products with oxygen is to use a membrane reactor to effectively segregate the reactant and product hydrocarbon molecules from the oxygen hydrogen scavenger. A third approach is to utilize redox agents along with the dehydrogenation catalysts that provide a supply of reactive but not free oxygen for reaction with the product hydrogen. One difficulty with this solution is that the redox agents are reduced and consumed in the process and must be regenerated in a separate processing step.

Butane Vapor-Phase Isomerization

Isomerization applications are to provide additional feedstock for alkylation units or high-octane fractions for gasoline blending. Straight-chain paraffins (*n*-butane) are converted to respective *iso*-compounds by continuous catalytic (aluminum chloride and noble metals) processes. Natural gasoline or light straight-run gasoline can provide feed by first fractionating as a preparatory step. High volumetric yields (>95%) and 40 to 60% conversion per pass are characteristic of the isomerization reaction.

The butane vapor phase isomerization process is a process for isomerizing *n*-butane to *iso*-butane using aluminum chloride catalyst on a granular alumina support and with hydrogen chloride as a promoter. A non-regenerable aluminum chloride catalyst is employed with various carriers in a fixed-bed or liquid contactor. Platinum or other metal catalyst processes utilize a fixed-bed operation and can be regenerable or non-regenerable. The reaction conditions vary widely depending on the particular process and feedstock, 40 to 480°C (100 to 900°F) and 150 to 1,000 psi; residence time in the reactor is 10 to 40 minutes.

The butane vapor phase isomerization process is a process for isomerizing *n*-butane to *iso*-butane using aluminum chloride catalyst on a granular alumina support and with hydrogen chloride as a promoter.

Butanol

Butanol (butyl alcohol) is a four-carbon alcohol that can be obtained by fermentation from the same feedstocks used in ethanol fermentation. Some properties of butanol are superior to ethanol for fuel – butanol has more energy/gallon than ethanol, it does not absorb water easily which unlike ethanol may allow it to be transported via gasoline pipeline, and butanol-gasoline blends have lower vapor pressure than ethanol-gasoline blends which is important in reducing evaporative hydrocarbon emissions. The obvious advantages of butanol are the high octane rating (over 100) and high energy content, only approximately 10% lower than gasoline, and subsequently approximately 50% more energy-dense than ethanol, 100% more so than methanol. The major disadvantage of butanol is the high flash point (35°C, 95°F).

Traditionally, butanol is fermented from *Clostridium acetobutylicum* via the so-called ABE (acetone-butanol-ethanol) fermentation. ABE fermentation yields 3 parts acetone, 6 parts butanol, and 1 part ethanol (3:6:1). However, butanol from ABE fermentation is less economic than ethanol essentially because the fermentation is impeded by low concentrations of the products (end-product inhibition) requiring larger process stream volumes, reactors, and tanks.

Butene

Butene, also known as butylene, is an alkene with the formula C_4H_8 ($CH_3CH=CHCH_3$ or $CH_3CH_2CH=CH_2$) (Table B-31). The butene derivatives are colorless gases that are typically obtained by catalytic cracking of long-chain hydrocarbon derivatives during refining of crude oil. Cracking produces a mixture of products, and the butene is extracted from this by fractional distillation.

Table B-31 The defend isomers of butene (C_4H_8).

Common name(s)	Structure
α -butylene, 1-butene	
cis-2-butene, <i>cis</i> - β -butylene	
trans-2-butene, <i>trans</i> - β -butylene	
isobutylene, isobutene	

All four of these isomers are gases at room temperature and pressure but can be liquefied by lowering the temperature or raising the pressure. These gases are colorless, but do have distinct odors and are highly flammable. Although not naturally present in crude oil, they can be produced from by the catalytic cracking of crude oil and higher- molecular-weight crude oil products. Although they are stable compounds, the carbon-carbon double bonds make them more reactive than similar alkane derivatives, which are more inert compounds in various ways. Because of the double bonds, these 4-carbon alkene derivatives can act as monomers in the formation of polymers, as well as having other uses as petrochemical intermediates.

See also: Alkenes.

Butene Dehydrogenation

Butenes, 1-butene, cis-2-butene, trans-2-butene, and iso-butene, also known as butylenes, have a variety of commercial uses. Iso-butene is a primary reactant in the production of methyl tertiary butyl ether (MTBE), a major additive in reformulated gasoline and used to reduce emissions from automobile exhaust. Butenes are oligomerized and hydrogenated to produce higher alkanes for gasoline blend stock uses and can be reacted further to produce other commercially important products. It is estimated that 90% of butene consumption is in motor fuel applications such as alkylate, polymer gasoline, and oligomerized gasoline blend stocks. Butenes are also blended directly into gasoline and mixed with propane and butanes in LPG. Approximately 10% of the available butenes are used in chemical production where the most important products are butadiene, sec-butyl alcohol, butyl rubber, and polybutylene elastomer.

The butene derivatives are produced as by-products of many refinery processes. Due to the huge volumes of crude oil subjected to catalytic cracking, catalytic crackers are the single largest source of mixed butenes that are typically used for MTBE production. Cracking catalysts and conditions are sometimes formulated and selected to especially maximize the production of iso-butene. Steam cracking of olefins is another major source of by-product butenes.

Butenes are dehydrogenated further to produce butadiene. Butadiene is one of three copolymers in acrylonitrile-butadiene-styrene (ABS) plastic and styrene-butadiene (SB) rubber. Dehydrogenation reactions are endothermic, and those of butane and butene are no exception.

One goal of the various processes for producing either butenes or butadiene is to maximize feedstock conversion and simultaneously selectivity to the desired product isomer. For example, while mixed butenes are typically used for MTBE and polygas synthesis, polybutylene production requires higher purity 1-butene. The yield of each isomer is controlled by the reaction conditions employed. The recovered yield is controlled by the downstream separation steps applied to the mixture of product and un-reacted starting materials. The practical result of these sometimes conflicting demands are a wide range of conversion technologies and separation approaches, each more or less optimized for a specific end use application.

Maximization of the conversion of feed to product can be accomplished by reducing the vapor pressure of the products in the reactor. A common practice is to add steam to the reactor. This not only reduces the partial pressure of the products driving the conversion higher; it is typically also utilized to import the needed heat of reaction into the reaction vessel. Steam is used because it can be easily separated from the reactor effluent through condensation. A third approach is to utilize redox agents along with the dehydrogenation catalysts that provide a supply of reactive but not free oxygen for reaction with the product hydrogen. One difficulty with this solution is that the redox agents are reduced and consumed in the process and must be regenerated in a separate processing step.

C₁, C₂, C₃, C₄, C₅ Fractions

A common way of representing fractions containing a preponderance of hydrocarbon derivatives having 1, 2, 3, 4, or 5 carbon atoms, respectively, and without reference to hydrocarbon type.

Calorific Value

The calorific value is a direct indication of the heat content (energy value) of the fuel and represents the combined heats of combustion of the carbon, hydrogen, nitrogen, and sulfur in the organic feedstock and is the gross calorific value with a correction applied if the net calorific value is of interest.

The calorific value is usually expressed as the gross calorific value (GCV) or the higher heating value (HHV) and the net calorific value (NCV) or lower calorific value (LHV). The difference between the gross calorific value and the net calorific value is the latent heat of condensation of the water vapor produced during the combustion process. The gross calorific value assumes that the entire vapor produced during the combustion process is fully condensed. The net calorific value assumes that the water is removed with the combustion products without fully being condensed. To equalize all effects, the calorific value of the fuel should be compared based on the net calorific value basis. The calorific value varies considerably depending on the ash, moisture content, and the molecular type of the substance. The unit is calories per gram, which may be converted to the alternate units (1.8 Btu/lb = 1.0 kcal/kgm = 4.187 kJ/kgm).

The calorific value is neither part of the proximate analysis nor part of the ultimate analysis of a carbonaceous material, but it is, in fact, one of the many physical properties of fuels and, as such, in the present context, the importance of the calorific value as one of the means by which a fuel can be evaluated.

Camelina

Camelina sativa is a flowering plant in the family Brassicaceae and is usually known in English as camelina, gold-of-pleasure, false flax, wild flax, linseed dodder, German sesame, and Siberian oilseed which is native to Europe and to Central Asian areas. This plant is cultivated as an oilseed crop mainly in Europe and in North America.

Camelina is relatively easy to grow and requires few agricultural inputs compared to other crops. It can establish successfully through broadcast seeding on frozen ground in winter or early spring, even in previous crop stubble. Germination occurs after soil temperatures reach 3°C (38°F). Planting with grain drills works well, but results are generally no better than surface broadcasting when there is adequate moisture on the soil surface.

Camelina is generally grown as a summer annual oilseed crop, but it can be grown as a winter annual in milder climates. It is a short-season crop that matures in 85 to 100 days. The plants grow 1 to 3 feet tall and have branched stems that become woody as they mature, and the leaves are 2 to 3½ inches long, arrow-shaped, and pointed with smooth edges. The crop can be grown in arid conditions, prefers lower humidity levels, does not require significant levels of inputs such as fertilizer, and the oil will produce a high-quality biodiesel. Typical varieties of camelina are approximately 38 to 40% w/w oil. At least two firms are offering contracts to producers with stated goals of achieving two million acres of production.

Camelina oil can be used in both edible and industrial products. There is considerable variation in oilseed content among camelina plants from wild collections and old European varieties, and varieties with higher oilseed content

are under development. Camelina oil is relatively high in omega-3 fatty acids and low in saturated fatty acids. The oil also contains gamma tocopherol (vitamin E), which acts as an antioxidant and increases the stability and shelf life of camelina oil compared to other omega-3 oils.

Biodiesel produced from camelina has a variety of benefits. For example, Camelina-based aviation fuel could save 84% of carbon emissions biodiesel and can be produced from Camelina in large quantities.

Canola Oil

Canola is a type of rapeseed that is a member of the Brassica family, which includes broccoli, cabbage, cauliflower, mustard, radish, and turnip. Canola is a popular crop throughout the world because of its variety of uses and the nutritional value compared to competing crops. Canola can be produced in some countries where similar crops are not able to grow because of short growing seasons. In the United States, North Dakota is the leading producer of canola. Canola oil has been increasing its market share in the United States, because of its nutritional advantages compared to other competitive vegetable oils. Although canola oil would primarily move into edible markets, increased acreage for the plant will have positive impacts on the overall vegetable oil supply.

There are a number of steps involved in making biodiesel from the canola crop: (i) the oil is removed from the seed; the seed is crushed for the oil contained within and after the oil is extracted, the by-product is a protein rich meal that can be used by the livestock industry, (ii) the canola oil is placed in the mixer with methanol and potassium hydroxide (KOH) and mixed (iii) the mixture is transferred to the reaction vessel using the air compressor where the mixture is left to chemically react, and the glycerol is removed; (iv) a pneumatic diaphragm pump pushes the now-diesel from the reactor vessel to the first washing tank, where it is washed with a fine spray of water which removes the soaps that have formed as a by-product of the chemical process and allowed to settle, (v) the biodiesel moves to the second washing tank to be washed again, settled, and transferred to the cooker where the biodiesel is heated to 100°C (212°F) to boil off any excess water, and (vi) the biodiesel is then filtered into storage containers.

Capillary Forces

Capillary forces are the interfacial forces between immiscible fluid phases, resulting in pressure differences between the two phases. Capillary action, capillarity, capillary motion, or wicking is the ability of a substance to draw another substance into it. Such forces occur when the adhesive intermolecular forces between the liquid and a substance are stronger than the cohesive intermolecular forces inside the liquid. The effect causes a concave meniscus to form where the substance is touching a vertical surface. The same effect is what causes porous materials such as sponges to soak up liquids.

Capillary forces act at fluid-air-solid interfaces to minimize the surface energy of the interface. Surface tension or capillary forces scale with the perimeter of the wetted area. In the bulk region of a liquid, cohesive forces between the liquid molecules are balanced and shared with all the neighboring molecules. However, at the surface of the liquid, the molecules are not surrounded by liquid molecules on all sides and exert stronger attractive forces with neighboring molecules on and below the surface.

Surface tension is a consequence of the imbalances in attractive forces between molecules and is related to the decrease in surface energy that results from decreasing surface area. At the surface, a layer forms in which the molecules are strongly bonded, thereby making it harder to penetrate the surface of the liquid than to move submersed objects. Stronger interactions between molecules result in higher values of surface tension, while lower values indicate that the molecules are not interacting as strongly. The dimensions for surface tension are expressed as force per unit length or energy per unit area.

See also: Surface Tension.

Capillary Number

The capillary number (N_c) is the ratio of viscous forces to capillary forces, and equal to viscosity times velocity divided by interfacial tension. A common experimental observation is a relationship between residual oil saturation (S_{or}) and local capillary number (N_c). This relationship is called a capillary desaturation curve (CDC). The capillary number reflects the balance between viscous and capillary forces at the pore scale; viscous forces dominate at high capillary numbers, while capillary forces dominate at low capillary numbers. The capillary number at the pore scale can be defined as:

$$N_c = \frac{\mu v}{\gamma \cos \theta}$$

In this equation, μ is the water viscosity, v is the linear advance rate, γ is the oil-water interfacial tension, and θ is the contact angle.

If the viscous forces acting on the trapped oil exceed the capillary retaining forces, residual oil can be mobilized. This is reflected in CDC curves which show that while S_{or} values are constant at low values of the capillary number, they start to decrease above a certain value of the capillary number termed the critical capillary number.

Capillary Pressure

The capillary pressure is the pressure required to drive a fluid through a pore throat and displace the pore-wetting fluid. As pore throats become smaller, higher capillary pressures are required to displace the pore-wetting fluid. Capillary pressure curves are available that provide information regarding pore throat sorting, relative permeability, and reservoir quality. The size of the pore throat is related to the residual water saturation. Water cut is related to the capillarity and the distance above the oil-water contact. Capillarity is important to waterflood performance.

Carbohydrates

A carbohydrate is an organic compound, consisting only of carbon, hydrogen, and oxygen, with general formula $C_m(H_2O)_n$.

Carbohydrates are divided into four chemical groupings which are (i) monosaccharide derivatives, (ii) disaccharide derivatives, (iii) oligosaccharide derivatives, and (iv) polysaccharide derivatives. In general, the monosaccharides and disaccharides, which are smaller (lower molecular weight) carbohydrates, are commonly referred to as sugars. While the scientific nomenclature of carbohydrates is complex, the names of the monosaccharides and disaccharides very often end in the suffix *ose* – for example, glucose (a monosaccharide) and sucrose (a disaccharide).

The term carbohydrate is a synonym of saccharide, and the saccharides form a large family of natural carbohydrates that fill numerous roles in living things. Polysaccharides, such as starch and glycogen, serve for the storage of energy, and cellulose and chitin serve as structural components in plants and arthropods, respectively. The 5-carbon monosaccharide ribose is an important component of coenzymes such as adenosine triphosphate (ATP) and the backbone of the genetic molecules (ribonucleic acid, RNA). The related deoxyribonucleic acid is a component of DNA.

Carbohydrates (starch, cellulose, sugar derivatives) are readily obtained from wheat and potato, while cellulose is obtained from wood pulp. The structures of these polysaccharides can be readily manipulated to produce a range of biodegradable polymers with properties similar to those of conventional plastics such as polystyrene foams and polyethylene film. In addition, these polysaccharides can be hydrolyzed, catalytically or enzymatically to produce sugars, a valuable fermentation feedstock for the production of ethanol, citric acid, lactic acid, and dibasic acids such as succinic acid.

Carbonate Washing and Water Washing

Carbonate washing is a mild alkali process for emission control by the removal of acid gases (such as carbon dioxide and hydrogen sulfide) from gas streams and uses the principle that the rate of absorption of carbon dioxide by potassium carbonate increases with temperature.

The process is at maximum efficiency near the temperature of reversibility of the reactions:

The hot potassium carbonate process employs an aqueous solution of potassium carbonate (K_2CO_3) to remove both carbon dioxide (CO_2) and hydrogen sulfide (H_2S) from gas streams as well as carbonyl sulfide (COS) and carbon disulfide (CS_2), if present.

A high partial pressure of carbon dioxide is required to keep the potassium bicarbonate (KHCO_3) in solution, and hydrogen sulfide will not react if the carbon dioxide pressure is not sufficiently high. The process requires that the absorber and the stripper operate at elevated temperatures in the range of 110 to 115°C (230 to 240°F) – hence the name hot process.

In the process, the sour gas enters at the bottom of the absorber and flows countercurrently to the carbonate liquid stream and the sweet gas exits at the top of the absorber. The rich carbonate solution exits from the bottom of the absorber and is flashed in the stripper, where acid gases are driven off. The lean carbonate solution is pumped back to the absorber. The lean solution may or may not be cooled slightly before entering the absorber.

Water washing (water scrubbing), in terms of the outcome, is analogous to washing with potassium carbonate, and it is also possible to carry out the desorption step by pressure reduction. The absorption is purely physical, and there is also a relatively high absorption of hydrocarbon derivatives, which are liberated at the same time as the acid gases.

Water is also used as an absorbent for gas impurities since it offers some advantages such as (i) water is available at low cost, (ii) water can be used in simple scrubbing units with less concern over leakage than for organic solvents, and (iii) water can be used on a once-through basis, and (iv) water washing does not require heat loads, even if high pumping loads are needed.

See also: Gas Cleaning, Gas Processing, Gas Treating.

Carbonate Washing Process

The hot potassium carbonate process decreases the acid content of natural and refinery gas from as much as 50% to as low as 0.5% and operates in a unit similar to that used for amine treating. The process works best near the temperature of reversibility of the reactions:

The hot potassium carbonate process decreases the acid content of the gas stream from as much as 50% to as low as 0.5% and operates in a unit similar to that used for amine treating. The process using potassium phosphate is

known as phosphate desulfurization, and it is used in the same way as the Girbotol process to remove acid gases from liquid hydrocarbon derivatives as well as from gas streams. The treatment solution is a water solution of potassium phosphate (K_3PO_4), which is circulated through an absorber tower and a reactivator tower in much the same way as the ethanolamine is circulated in the Girbotol process; the solution is regenerated thermally.

Other processes include the Alkazid process, which removes hydrogen sulfide and carbon dioxide using concentrated aqueous solutions of amino acids. The Giammarco-Vetrocoke process is used for hydrogen sulfide and/or carbon dioxide removal. In the hydrogen sulfide removal section, the reagent consists of sodium or potassium carbonates containing a mixture of arsenite derivatives (such as sodium arsenite, $NaAsO_2$) and arsenate derivatives (such as sodium arsenate, Na_3AsO_4); the carbon dioxide removal section utilizes hot aqueous alkali carbonate solution activated by arsenic trioxide or selenous acid or tellurous acid.

Carbon Cycle

The carbon cycle is a cycle in which carbon is stored in the atmosphere in the form of carbon dioxide, which is absorbed by plants and converted to carbohydrates by the process of photosynthesis. The cycle then follows food chains, with carbohydrates being consumed by herbivores and then carnivores, being metabolized during the process of respiration. Carbon dioxide is returned to the atmosphere as animals exhale and when organic waste and dead organisms decay.

Thus, vegetation and animals are important stores of carbon, although carbon may be rapidly returned to the atmosphere if vegetation is burned. Soils are also important reservoirs for carbon. Atmospheric carbon dioxide is soluble in water, in which it forms carbonic acid, which forms bicarbonate ions and carbonate ions, which in turn form salts (such as the insoluble calcium carbonate, which accumulates in marine sediments, marine organisms, and carbonate rocks, such as limestone). Carbon is typically stored in these forms until it is released to the atmosphere by chemical weathering.

Along with the nitrogen cycle and the water cycle, the carbon cycle comprises a sequence of events that are key to make the Earth capable of sustaining life. The cycle describes the movement of carbon as it is recycled and reused throughout the biosphere, as well as long-term processes of carbon sequestration and release from carbon sinks.

See also: Biogeochemical Cycles, Ecological Cycles.

Carbon Dioxide

Carbon dioxide is a product of combustion that acts as a greenhouse gas in the atmosphere of the Earth, trapping heat and contributing to climate change.

Carbon dioxide is colorless. At low concentrations, the gas is odorless. At higher concentrations, it has a sharp, acidic odor. It will act as an asphyxiant and an irritant. When inhaled at concentrations much higher than usual atmospheric levels, it can produce a sour taste in the mouth and a stinging sensation in the nose and throat. These effects result from the gas dissolving in the mucous membranes and saliva, forming a weak solution of carbonic acid.

The carbon dioxide molecule ($O=C=O$) contains two double bonds and has a linear shape. It has no electrical dipole, and as it is fully oxidized, it is moderately reactive and is non-flammable. At standard temperature and pressure, the density of carbon dioxide is approximately 1.5 times that of air. Above -78.51°C (-109.3°F), carbon dioxide changes directly from a solid phase to a gaseous phase through sublimation (passing directly into the gas phase leaving no liquid), or from gaseous to solid through deposition. Liquid carbon dioxide forms only at pressures above 75 psi.

See also: Carbon Monoxide.

Carbon Dioxide Balance

The carbon dioxide emissions of fuels can be split into emissions during use and upstream emissions. For oil fuels, the emissions during use are the most important ones. Hydrogen does not result in carbon dioxide emissions during use, and the emissions from biofuels such as ethanol are balanced by the carbon dioxide captured during biomass growth.

The upstream emissions for many renewable fuels can be substantial. However, for large-scale production processes, carbon dioxide can be captured and stored underground. This can reduce upstream emissions by 85 to 95%. Depending on the primary fuel choice and the combustor, upstream emissions can vary substantially.

Synfuels from gas and coal result in similar emissions to those from crude oil-derived fuels. However, substantial emissions reductions are possible when fuels from biomass and hydrogen from fossil fuels are introduced.

See also: Biofuels, Carbon Dioxide.

Carbon Dioxide Gasification

The reaction of a carbonaceous feedstock (using coal as the example) with carbon dioxide may be approximated or simplified as the reaction of carbon with carbon dioxide, for modeling purpose. Carbon dioxide reacts with carbon to produce carbon monoxide (Boudouard reaction), which is an exothermic reaction:

The reverse reaction is carbon deposition reaction that is a major culprit of carbon fouling on many surfaces, such as process catalyst deactivation. This gasification reaction is thermodynamically favored at high temperatures (>680°C, >1255°F), which is also quite similar to the steam gasification.

The reaction, if carried out alone, requires high temperature (for fast reaction) and high pressure (for higher reactant concentrations) for significant conversion. However, this reaction in practical gasification application is almost never attempted as a solo chemical reaction, due to a variety of factors such as low conversion, slow kinetic rate, and low thermal efficiency.

There is general agreement that experimental data on the rate of carbon gasification by carbon dioxide fit an empirical equation of the form:

$$r = k_1 p_{\text{CO}_2} / (1 + k_2 p_{\text{CO}} + k_3 p_{\text{CO}_2})$$

In this equation, p_{CO} and p_{CO_2} are partial pressures of CO and CO₂ in the reactor. This rate equation is shown to be consistent with at least two mechanisms where carbon monoxide retards the gasification reaction.

Mechanism A:

Mechanism B:

In both mechanisms, carbon monoxide retards the overall reaction rate. In Mechanism A, retardation occurs via carbon monoxide adsorption onto the free sites, while in Mechanism B, retardation occurs via reaction of chemisorbed oxygen with gaseous carbon monoxide to produce gaseous carbon dioxide.

See also: Carbon Dioxide, Carbon Monoxide.

Carbon Dioxide Recovery

Carbon dioxide recovery processes recover high purity carbon dioxide from gas streams such as boiler flue gases, gas turbine exhausts, and waste gases using absorption/stripping technology to reduce sulfur dioxide levels.

The system is based on absorption/ stripping using a 15% to 20% monoethanolamine (MEA) solution. Feed gases are sent to an amine absorber where they are scrubbed with MEA to recover carbon dioxide. The scrubbed gases are vented to the atmosphere after water washing in the absorbers top to minimize MEA losses. Rich solution from the MEA absorber is preheated in an exchanger, flashed, and sent to stripper where carbon dioxide is recovered overhead. Condensate from the stripper overhead is returned to the system.

Lean mono-ethanolamine from the stripper is cooled, filtered, and returned to the absorber. Periodically, a batch reclaiming operation is conducted to purge mono-ethanolamine degradation products and to recover mono-ethanolamine by decomposing heat-stable salts. The bottoms from the reclaiming operation may be burned as boiler fuel.

Carbon dioxide recovered from the stripper overhead may be compressed and used as a vapor product, or dried and liquefied using a standard ammonia refrigeration system to produce a liquid product.

Operating units have exhibited availability factors in excess of 98%. Absorption and stripping operations take place at slightly above atmospheric pressure. Feed gas can contain up to 15 vol% oxygen, though economics are favored by high carbon dioxide and low oxygen concentrations in the feed. The process can recover carbon dioxide from flue gases containing from 3 to 15 vol% (dry basis) carbon dioxide. Moderate levels of sulfur dioxide and nitrogen oxides in the feed are acceptable. Sulfur dioxide pre-scrubbing is required only with sulfur dioxide levels higher than 100 ppm v/v.

See also: Gas Cleaning, Gas Processing, Gas Treating.

Carbonization

Carbonization is another form of pyrolysis which can convert over one-half of a scrap tire into usable products. Carbonization processes operate at much higher temperatures than typical pyrolysis units. At this higher temperature condition, the main product is char. The char is purified into carbon black, one of the main components in the manufacture of tires.

The carbonization process was originally developed for the production of charcoal from wood and the production of coke from coal. Nevertheless, the process can (and already has) found use in the production of fuels from carbonaceous feedstocks such as biomass.

In the process, the feedstock is converted to carbonaceous volatile products (gases and liquids) and a high-carbon product the removal of volatile materials (gases and condensable liquids, such as bio-oil) and thermal decomposition products (devolatilization) and is usually achieved by the use of temperatures up to 1,500°C (2,730°F). The degradation of the feedstock is severe at these temperatures and produces substantial yields of volatile products, in addition to the high-carbon non-volatile product. The low-temperature carbonization is achieved by the use of temperatures of on the order of 500 to 700°C (930 to 1,290°F) – the temperature range for medium-temperature carbonization processes is self-explanatory.

Four main types of products are obtained by low-temperature carbonization processes: (i) gases, (ii) condensable liquids, (iii) tar, and (iv) char. The proportions are determined by the properties and type of feedstock and by the rate and the residence time of the feedstock and the primary products in the hot zone.

Both fluidized-bed and fixed-bed systems have been used; the former system requires direct contact with another heating medium, whereas fixed-bed systems may be heated directly or indirectly. Carriers can vary, and among the carriers for direct heating are steam, air, recycle gases, sand, and metal balls containing a salt to take advantage of the latent heat of fusion. Superheated steam at 540 to 650°C (1,000 to 1,200°F) has been effective. For any particular feedstock, the yield of gases increases with the carbonization temperature while the yield of the solid (char, coke) product decreases. The yields of tar and low-molecular-weight liquids are to some extent variable but are greatly dependent on the process parameters, especially temperature as well as the type of feedstock.

Water has a tendency to reduce the rate of carbonization when certain low-rank coals are employed but is often responsible for increased tar yields. The usual thermal decomposition of the feedstock (i.e., decomposition in the absence of added species) may be markedly influenced by oxidation or by hydrogenation of the feedstock prior to the thermal process; the presence of mineral matter may also be influential.

Carbon Monoxide

Carbon monoxide (CO) is a lethal gas produced by incomplete combustion of carbon-containing fuels in internal combustion engines. The gas is colorless, odorless and tasteless, which is highly toxic to humans and animals. It is the simplest oxo-carbon, and is (chemically) an anhydride of formic acid (HCOOH).

Carbon monoxide is produced from the partial (or incomplete) oxidation of carbon-containing compounds and forms when there is insufficient oxygen to produce carbon dioxide (CO₂). The gas burns with a blue flame, producing carbon dioxide.

Carbon monoxide is one of the most common and widely distributed air pollutants. Carbon monoxide has a slightly lower density than air. In the human body, it reacts readily with hemoglobin to form carboxy-hemoglobin.

See also: Carbon Dioxide.

Carbon Residue

The carbon residue is the amount of carbonaceous residue remaining after thermal decomposition of a carbonaceous fuel or fuel source in a limited amount of air; also called the carbon-forming propensity; also called the Conradson carbon residue or the Ramsbottom carbon residue or the microcarbon residue in reference to the inventor of the respective test methods.

Fuels are mixtures of many compounds that differ widely in their physical and chemical properties. Some of them may be vaporized in the absence of air at atmospheric pressure without leaving an appreciable residue. Other non-volatile compounds leave a carbonaceous residue when destructively distilled under such conditions. This residue is known as carbon residue when it is determined in accordance with a prescribed test procedure.

The carbon residue is a property that can be correlated with several other properties of crude oil; hence, it also presents indications of the volatility of the crude oil and the carbon-forming (or inversely the distillate-producing) propensity. However, tests for carbon residue are sometimes used to evaluate the carbonaceous depositing characteristics of fuels used in certain types of fuel-burning equipment.

The mechanical design and operating conditions of such equipment have such a profound influence on carbon deposition during service that comparison of carbon residues between oils should be considered as giving only a rough approximation of relative deposit-forming tendencies. A more precise relationship between carbon residue and hydrogen content, H/C atomic ratio, nitrogen content, and sulfur content has been shown to exist. These data can provide more precise information related to the anticipated behavior of a variety of feedstocks in thermal processes.

Because of the extremely small values of carbon residue obtained by the Conradson and Ramsbottom methods when applied to the lower-boiling distillate fuel oils, it is customary to distill such products to 10% residual oil and determine the carbon residue thereof. Such values may be used directly in comparing fuel oils, as long as it is kept in mind that the value is that for a residuum and is not to be compared with the carbon residue of the whole feedstock.

Carbon Sink

A carbon sink is a geographical area whose vegetation and/or soil soak up significant carbon dioxide from the atmosphere. Such areas, typically in tropical regions, are increasingly being sacrificed for energy crop production.

A carbon sink is a reservoir that can absorb or sequester carbon dioxide from the atmosphere and include forests, soils, peat, permafrost, ocean water, and carbonate deposits in the deep ocean. Most of these carbon sinks are large and slow moving; human influence on these sinks is generally deemed fairly minimal, with the possible exception of soils and agriculture.

The most commonly referenced form of carbon sink is that of forests. Plants and trees absorb carbon dioxide from the atmosphere via photosynthesis, retain the carbon component as the building block of plant fiber, and release oxygen back into the atmosphere. Therefore, long-lived, high-biomass plants, such as trees and forests, represent effective carbon sinks as long as they are maintained.

Certain gases, such as chlorofluorocarbons, contribute twofold to climate change by simultaneously trapping reflected heat and thinning the protective ozone layer. This ozone depletion reduces the ability of the atmosphere to absorb and reflect solar radiation. As a result, more solar radiation is able to reach the surface of the Earth and potentially accelerate the process of climate change.

Oceans are also carbon dioxide sinks and represent the largest active carbon sink on Earth, absorbing more than a quarter of the carbon dioxide that humans put into the air.

Carbo-V Process

The Carbo-V gasification process presents an innovative and efficient way of converting biomass feedstock into clean, tar-free, and low-methane synthesis gas. Thereby, the three-stage Carbo-V gasification process combines the advantages of an entrained flow gasification originating from coal utilization with an innovative pre-conditioning of the solid biomass which is done by a thermal process (pyrolysis) referred to as low temperature gasification.

In a first process step (the low temperature gasification step), the wood chips are thermally cracked at temperatures between 400 and 500°C (740 and 930°F). The products of this pyrolysis decomposition are charcoal and a pyrolysis gas containing the volatiles components of the wood diluted in the gasification agent. The necessary heat for this pyrolysis process is gained by oxidizing a small amount of the charcoal in the low temperature gasification step. This oxidation is performed by a gasification agent gas which consists of a mixture of oxygen and saturated steam. This mixture is fed to the low temperature gasification step through nozzles at the bottom of the reactor. The char from each low temperature gasification step is cooled, de-compressed to atmospheric pressure, screened, grinded, stored, and then fed to the high temperature gasifier.

In the second process step, the pyrolysis gas as well as the recycled residual coke is further oxidized with pure oxygen in the combustion chamber of the high temperature gasifier at temperatures above the melting point of the fuel ash. Thus, the hydrocarbon-rich pyrolysis gas will be converted to a hydrocarbon-free process gas consisting only of carbon monoxide, carbon dioxide, hydrogen, and steam.

In the third process step, char from the storage silo is fed to the endothermic part of the Carbo-V gasifier via a chamber sluice. The hot process gas from the burning chamber now reacts with the char in the gasification reactor of the high temperature gasifier. Thus:

These reactions are strongly endothermic, and the chemical reactions cool down the gas within the reaction vessel by more than 500°C (930°F). This procedure is also called “chemical quenching” and is one of the major features of the Carbo-V gasification process. It allows keeping a high heating value of the product gas. The crude synthesis gas leaving the high temperature gasifier is now further cooled down to below 200°C via a specially designed gas cooling system. The heat from the gas cooling system is used to produce high pressure steam (up to a maximum of 1,350 psi).

Following the gas cooling system, the crude gas loaded with dust, residual carbon, and the ash components of the feedstock has to be cleaned from solid particles. This occurs in a two-stage de-dusting system. The coarse particles are separated by a gas cyclone followed by a bag house filter system for the fine de-dusting. The residual coke is de-compressed over a chamber sluice and discharged from the system. After grinding of the residual coke to a suitable size, the solid fraction also containing the ash components is fed back to the burner of the high temperature gasifier by a fluidized dense flow steam.

A small portion of the filter dust is removed from the process to prevent the enrichment of impurities in the residual coke circuit. Due to the high gasification temperature in the burning chamber of the high temperature gasifier, the ash components get melted. The melted ash forms a solid layer on the refractory material within the burning chamber which protects the refractory material from thermal stresses, thus permitting long life times of the refractory material. The melted ash trickles down at the wall of the gasifier and is collected in a water basin below the gasifier. In the water basin, the melted ash is rapidly cooled and converted to a slag granulate. The vitrified slag will be periodically discharged from the gasifier over a chamber sluice.

Carbureted Blue Gas

Carbureted blue gas is a mixture of carbon monoxide and hydrogen formed by the action of air and then steam on hot coal or coke and enriched with hydrocarbon gases during its manufacture by a simultaneous process when low-boiling distillate, gas oil, or fuel oil are gasified. The gas has a gross heat content of approximately 500 to 550 Btu/ft³.

See also: Blue Gas, Carbureted Water Gas.

Carbureted Water Gas

Carbureted water gas is the result of combining the water gas and oil gas methods. Briefly, oil gas is the gas formed by the thermal cracking of crude oil. If oil is sprayed onto heated checker work (refractory), it cracks to form lower gaseous hydrocarbon derivatives. The types of hydrocarbon derivatives depend entirely on the type of feedstock but do cause an increase in the heat content of the product gas.

In the oil gas method, an oil product (typically heavy fuel oil, as described above) is sprayed into the hot water gas chamber to produce a better quality (higher heat content) gas. The amount of the heavy fuel ratio is a determinant of the quality of the gas. In the 19th century and early 20th century, this was the method used to produce the town gas but has largely been superseded by natural gas in countries with an abundant supply. As supplies of natural gas diminish and various carbonaceous feedstocks are used for gas production, the process may once again rise in importance.

Catalysts

A catalyst is a chemical agent which, when added to a reaction (process), will enhance the conversion of a feedstock without being consumed in the process.

Catalysts are indispensable in the fuel production and refining and petrochemical industry for routine production of gasoline, diesel fuels, jet fuels, heavy oil hydrocarbon derivatives, petrochemicals, and plastics. Hydrocarbon derivatives (HT and HDS) and residue hydrodesulfurization (RDS) are the major processes for converting crude oil into these crude oil products.

During processing, catalysts will become contaminated with impurities in the crude oil feed and become deactivated. When that happens, they are usually sent for regeneration where contaminants are removed. Ultimately, they will be contaminated with coke, sulfur, vanadium, and nickel in a manner and at a level that makes regeneration impractical. At this stage, catalysts are considered *spent* and they may pose significant environmental problems, as landfill disposal is no longer accepted as best practice.

Hydrodesulfurization (HDS/RDS) of heavy oil produces spent catalysts that contain molybdenum (Mo), vanadium (V), nickel (Ni), or cobalt (Co) at concentration levels that have been found to be economical for recovery. Due to its complex nature, metal recovery from the spent catalysts from hydrodesulfurization processes involves a combination of pyro- and hydro-metallurgical processes. With increasing demand of ever more complex metallic

composite and alloy materials in modern manufacturing processes, it becomes imperative to develop appropriate methods for the recovery of these valuable metals.

See also: Refining.

Catalysts – Activity

The ratio of the space velocity of the catalyst under test to the space velocity required for the standard catalyst to give the same conversion as the catalyst being tested; usually multiplied by 100 before being reported.

A catalyst is a substance that increases the rate of a chemical reaction without itself undergoing any permanent chemical change. Catalysts that have the same phase as the reactants are homogeneous catalysts (e.g., enzymes in biochemical reactions or transition-metal complexes used in the liquid phase for catalyzing organic reactions). Those that have a different phase from the reactants are heterogeneous catalysts (e.g., metals or oxides used in many industrial gas reactions).

As a catalyst takes part in the chemical reaction, but is not consumed by the reaction, the catalyst must be a reactant in one of the first steps in the mechanism and a product in one of the last steps. The reaction proceeds in a cyclic fashion, where the catalyst, or more correctly the catalytic sites, are regenerated and used again and again. The catalyst provides an alternative pathway by which the reaction can proceed, in which the activation energy is lower. It thus increases the rate at which the reaction comes to equilibrium, although it does not alter the position of the equilibrium. The catalyst itself takes part in the reaction and consequently may undergo physical change (e.g., conversion into powder). In certain circumstances, small quantities of catalyst can speed up reactions. Most catalysts are also highly specific in the type of reaction they catalyze, particularly enzymes in biochemical reactions. Generally, the term is used for a substance that increases reaction rate (a positive catalyst). Some reactions can be slowed down by negative catalysts.

The increase in the rate of a specified chemical reaction caused by catalyst under specified conditions is called catalytic activity. Activity of a catalyst is a measure of the rate of conversion of the starting material by the catalyst. For homogeneous catalysts, activity is expressed as rate constant per mole of catalyst. For heterogeneous solid catalysts, the activity is generally expressed as reaction rate or the rate constant per unit mass, volume, or surface area of the catalyst. In general, the catalyst activity can be defined as the fractional conversion of starting material under standardized conditions.

The activity of a catalyst is determined by measuring the specific rate of the catalyzed reaction in which the desired product forms. The specific rate of the catalytic reaction is the rate increase caused by unit mass, volume, or surface area of catalyst compared to the rate of uncatalyzed reaction. This is usually represented by a power rate equation. For example, for a reaction $A + B \rightarrow C$, the reaction rate r is represented by the following equation:

$$r = k c_A^a c_B^b c_C^c$$

In this equation, k is the reaction rate constant; c_A , c_B , and c_C are the concentrations (partial pressures) of the reactants and product; and a , b , and c are the respective orders of reactions.

The reaction rate or the catalyst activity is dependent on the temperature. This relation is represented by the following equation:

$$r = A \exp (-E/RT)$$

where A is the pre-exponential factor and E is the apparent activation energy. From this equation, the catalyst activity is exponentially proportional to the temperature. Activity can generally be stepped up by raising the temperature, although frequent raising of the temperature can shorten the life of the catalyst or increases undesirable reactions that may be catalytic, thermal, or both. A higher temperature can also decrease the maximum conversion obtainable if the reaction is exothermic and is limited in extent by thermodynamic equilibrium.

Other factors being equal, the activity of a solid catalyst increases with its surface area exposed to the reactants. The activity of the exposed surface is generally not uniform throughout the available surface area. For example, the activity of a supported metal catalyst resides in the exposed metal atoms dispersed on the support, while the bare support is generally inactive. Because the number of exposed metal atoms per unit mass or unit volume of the catalyst can be determined by chemisorption measurement, catalytic activity can, in these cases, be defined in terms of the number of reactant molecules converted per exposed metal atom per second. This measure of activity is the turnover number or turnover frequency. This number essentially characterizes the rate of reaction per active site, and therefore the method used for determination of the number of exposed active atoms must be carefully selected and clearly specified. The activity of a catalyst can, then, be written as a product of two factors, the number of active sites, and the turnover frequency. For well-defined homogeneous catalytic reactions, the turnover number can be directly determined by calculating the number of molecules converted per second per catalyst molecule in solution.

Apart from activity, the usefulness of the catalyst also depends on its selectivity and stability. Selectivity is a measure of the relative rate of formation of each product from two or more competing reactions, and is usually expressed as a fraction or percentage of the total conversion. Of particular importance is the selectivity for the desired reaction product. A catalyst may be useful for its activity or its selectivity or both. If a variety of reactions are possible, then selectivity is more important. Stability of the catalyst toward chemical, thermal, or mechanical degradation or decomposition determines the useful life of the catalyst during which it maintains both its activity and selectivity at the fixed levels. Catalyst stability is also referred to as catalyst life, and a number of different processes can contribute to the loss of catalytic activity including coking, fouling, sintering, and poisoning. These catalyst deactivation processes are briefly discussed below.

Catalyst – Deactivation

Catalysts suffer a decline in activity with time-on-stream (*catalyst deactivation*). The time frame for this decline is large compared to the cycle of the transformation of a molecule of reactant to product, but brief in contrast to the natural enzyme. For example, the lifetime of a cracking catalyst is of the order of seconds while that of a reforming catalyst or that of the promoted catalyst in the synthesis of ammonia is measured in years.

Catalyst regeneration can restore catalyst activity. For example, coking catalysts can be restored by oxidation. However, other instances of catalyst deactivation such as sintering and/or irreversible phase transformation may be difficult to regenerate. In addition, catalyst deactivation by poisoning refers to the reversible/irreversible adsorption of small quantity of material on the active sites of the catalyst surface. The adsorbed material may be an impurity in the feed or an unwanted product of the reaction.

See also: Catalyst, Refining.

Catalyst Fouling

Fouling is a physical phenomenon in which coke or other inorganic foulants are deposited on the catalyst surface blocking the active sites and pores. The generic name coke indeed represents a variety of carbonaceous deposits widely varying in chemical nature. It varies from graphitic filamentous carbon to amorphous polymeric films. Coke formed from the gas phase reactions are more carbonaceous, while coke formed in liquid phase reactions may contain polycyclic aromatic molecules. Different types of cokes require different types of regeneration techniques and operating environments. Carbonaceous deposits can be removed by gasification using steam and air.

Coke is preferably gasified by reaction with oxygen as it is fast and efficient, but careful temperature control is needed to avoid the exothermic heat of reaction effecting thermal reorganization. To achieve temperature control, gasification by steam can be carried out with exothermic gasification by oxygen. Control can be achieved by conducting the gasification in two or more stages as is done in reforming catalysts. A mixture of steam and air is employed with a maximum of 2% air in the mixture. After gasification, nitrogen purging followed by reduction with hydrogen at 310°C (590°F) is carried out.

In the steam reforming process, the nickel catalyst supports both carbon formation and removal but potassium oxide (K_2O) or magnesium oxide (MgO , also called magnesia) is added to the catalyst only to increase the degree of coke gasification.

Inorganic foulants can be removed from catalyst by washing. A contamination from lubricating oil on emission control catalyst can result in phosphorus-glazed coatings. Such coatings must be removed by controlled dissolution and washing without seriously damaging the catalyst.

Methanation catalyst can sometimes be contaminated by carry-over from the carbon dioxide removal section. Although contaminants like potassium carbonate do not poison the catalyst, they physically block the catalyst surface and reduce the effectiveness. Such catalysts can be reactivated by back washing with clean condensate. While monoethanolamine and diethanolamine can also be washed off successfully, satisfactory reactivation of catalyst contaminated with sulfinol or vetrocoke solutions is difficult.

Solid acid catalysts for alkylation have recently received interest as an alternative to environmentally hazardous liquid phase catalysts such as sulfuric acid and hydrogen fluoride. The coke formed during the isobutane alkylation with C_4 olefins with Y zeolite catalysts is highly hydrogenated. Upon heating at low temperatures, this coke desorbs as hydrocarbon derivatives and simultaneously changes from an aliphatic structure to an aromatic one. This modification is the reason of the difficulty found in completely removing the coke from these types of catalysts. Combining an initial treatment in ozone followed by a treatment in hydrogen (H_2) or helium (He) helps the regeneration process.

Catalysts – Hydrogen Production

Hydrogen plants are one of the most extensive users of catalysts in the refinery. Catalytic operations – in which the catalyst is an important (necessary) aspect of the hydrogen production process – include (i) steam reforming, (ii) shift conversion, and (iii) methanation.

Reforming Catalysts

The reforming catalyst is usually supplied as nickel oxide that, during start-up, is heated in a stream of inert gas, then steam. When the catalyst is near the normal operating temperature, hydrogen or a light hydrocarbon is added to reduce the nickel oxide to metallic nickel. The high temperatures (up to 870°C , $1,600^\circ\text{F}$) and the nature of the reforming reaction require that the reforming catalyst be used inside the radiant tubes of a reforming furnace. The active agent in reforming catalyst is nickel, and normally, the reaction is controlled both by diffusion and by heat transfer. Catalyst life is limited as much by physical breakdown as by deactivation.

Sulfur is the main catalyst poison, and the catalyst poisoning is theoretically reversible with the catalyst being restored to near full activity by steaming. However, in practice, the deactivation may cause the catalyst to overheat and coke, to the point that it must be replaced. Reforming catalysts are also sensitive to poisoning by heavy metals, although these are rarely present in low-boiling hydrocarbon feedstocks and in naphtha feedstocks. Coke deposition on the reforming catalyst and ensuing gloss of catalyst activity are the most characteristic issues that must be assessed and mitigated.

A common steam-methane reforming catalyst uses nickel on an alpha-alumina ceramic carrier that is acidic in nature. Promotion of hydrocarbon cracking with such a catalyst leads to coke formation from higher boiling feedstocks. Some catalyst formulations use a magnesia/alumina (MgO/Al_2O_3) support that is less acidic than α -alumina that reduces cracking on the support and allows higher boiling feedstocks (such as liquefied petroleum gas) to be used.

Shift Conversion Catalysts

The second important reaction in a steam reforming plant is the shift conversion reaction:

Two basic types of shift catalyst are used in steam reforming plants: iron/chrome high-temperature shift catalysts, and copper/zinc low-temperature shift catalysts.

High-temperature shift catalysts operate in the range of 315 to 430°C (600 to 800°F) and consist primarily of magnetite (Fe_3O_4) with three-valent chromium oxide (Cr_2O_3) added as a stabilizer. The catalyst is usually supplied in the form of ferric oxide (Fe_2O_3) and six-valent chromium oxide (CrO_3) and is reduced by the hydrogen and carbon monoxide in the shift feed gas as part of the start-up procedure to produce the catalyst in the desired form. However, caution is necessary since if the steam/carbon ratio of the feedstock is too low and the reducing environment too strong, the catalyst can be reduced further, to metallic iron. Metallic iron is a catalyst for Fischer-Tropsch reactions, and hydrocarbons will be produced.

Low-temperature shift catalysts operate at temperatures on the order of 205 to 230°C (400 to 450°F). Because of the lower temperature, the reaction equilibrium is more controllable and lower amounts of carbon monoxide are produced. The low-temperature shift catalyst is primarily used in wet scrubbing plants that use a methanation for final purification. Pressure swing adsorption plants do not generally use a low-temperature since any unconverted carbon monoxide is recovered as reformer fuel. Low-temperature shift catalysts are sensitive to poisoning by sulfur and are sensitive to water (liquid) that can cause softening of the catalyst followed by crusting or plugging.

The catalyst is supplied as copper oxide (CuO) on a zinc oxide (ZnO) carrier, and the copper must be reduced by heating it in a stream of inert gas with measured quantities of hydrogen. The reduction of the copper oxide is strongly exothermic and must be closely monitored.

Methanation Catalysts

In wet scrubbing plants, the final hydrogen purification procedure is methanation in which the carbon monoxide and carbon dioxide are converted to methane:

The active agent is nickel, on an alumina carrier.

The catalyst has a long life, as it operates under ideal conditions and is not exposed to poisons. The main source of deactivation is plugging from carry-over of carbon dioxide from removal solutions.

The most severe hazard arises from high levels of carbon monoxide or carbon dioxide that can result from breakdown of the carbon dioxide removal equipment or from exchanger tube leaks that quench the shift reaction. The results of breakthrough can be severe, since the methanation reaction produces a temperature rise of 70°C (125°F) per 1% of carbon monoxide or a temperature rise of 33°C (60°F) per 1% of carbon dioxide. While the normal operating temperature during methanation is approximately 315°C (600°F), it is possible to reach 700°C (1,300°F) in cases of major breakthrough.

Catalysts – Methanation

In wet scrubbing plants, the final hydrogen purification procedure is methanation in which the carbon monoxide and carbon dioxide are converted to methane:

The active agent is nickel, on an alumina carrier.

The catalyst has a long life, as it operates under ideal conditions and is not exposed to poisons. The main source of deactivation is plugging from carry-over of carbon dioxide from removal solutions.

The most severe hazard arises from high levels of carbon monoxide or carbon dioxide that can result from breakdown of the carbon dioxide removal equipment or from exchanger tube leaks that quench the shift reaction. The

results of breakthrough can be severe, since the methanation reaction produces a temperature rise of 70°C (125°F) per 1% of carbon monoxide or a temperature rise of 33°C (60°F) per 1% of carbon dioxide. While the normal operating temperature during methanation is approximately 315°C (600°F), it is possible to reach 700°C (1,300°F) in cases of major breakthrough.

Catalyst Poisoning

A catalyst poison is an impurity present in the feed stream that reduces catalyst activity. It adsorbs on active sites of the catalyst. This adsorption can be temporary or permanent depending on the strength of adsorption of the poison on the surface of the catalyst. In a multi-reaction environment, the poisoning may affect one reaction step more than another. In such cases, the selectivity toward a desired reaction may be improved by deliberate addition of a poison.

The strong interaction between some feed component and one or more of the products and the active sites of catalyst may change the nature of surface and catalytic activity leading to poisoning. Impurities such as organic bases for acidic catalysts or sulfur compounds over metal containing catalysts strongly chemisorb resulting in severe deactivation. A ppm level of sulfide in gas phase is sufficient to significantly cover the metal surface with sulfur. The first group of poisons involves Group VA and VIA elements, poison metal catalysts by interaction through their S and P orbitals. The strategy of changing the number of bonding electrons by oxidation or reduction can effectively reverse the poisoning. Thus, the poison efficiency of sulfur increases as $\text{SO}_4^{2-} < \text{SO}_2 < \text{H}_2\text{S}$. For hydrogenation of 2-butanone to 2-butanol at 373 K and 1.7 MPa, the complete activity recovery of Ni-supported catalyst with supercritical CO_2 extraction at 313 K and 41 MPa was found to be the best regeneration procedure. Sulfur poisoning of nickel catalysts is very frequent in industrial operations. The treatment for regeneration of a Ni/SiO₂ catalyst that was completely poisoned by thiophene during the benzene hydrogenation consisted of a sequence of oxidation-reduction treatments using low oxygen partial pressure mixtures and pure hydrogen, with intermediate argon stream purging at the same treatment temperature. This method is easy to carry out and quickly recovers up to 90% w/w of the sulfur.

The second group of poisons involves toxic heavy metals such as lead (Pb), mercury (Hg), cadmium (Cd), and copper (Cu) that may form alloys with the catalyst. These poisons can be removed by abrasion or leaching. The third group of poisons is highly specific in strongly chemisorbing to a catalyst surface. Thus, for example, carbon monoxide poisons iron, but has negligible effect on copper or silver catalysts.

When high temperature shift catalysts are used with cyclic reformers, they get sulfided and contaminated with gums and carbon formed in the up-stream plant. Normally, the catalysts are regenerated by treatment with steam and air. Low temperature shift catalysts are more difficult to regenerate. The catalyst is first re-oxidized for removal of the sulfur poison, which is further washed with condensate to remove water-soluble poisons such as sulfate and chlorides. The treated catalyst is finally re-reduced.

Catalyst Regeneration

Most chemical processes use catalyst(s) as an aid to transform raw materials into finished products. The life of a catalyst varies from a fraction of a few seconds to several years depending on the severity and type of processes involved. All the catalysts used in chemical industries therefore come for regeneration at some time or the other. Alternatively, the catalysts have to be treated for recovery of their contents before being discarded for landfill operation. The decision of regeneration for catalysts is economical in nature and involves a trade-off between cost of regeneration and stringent requirement of environmental regulations.

Catalyst regeneration can be carried out in-situ within the same reactor at the site. Current environmental legislation and waste handling problems are, however, sufficiently discouraging that most companies favor ex-situ or off site regeneration. Carbonaceous and sulfur-containing deposits on the catalyst surface and pores are eliminated during the regeneration process and brought down to levels below 1 to 2% with 90-95% restoration of catalytic activity. Typically, parameters such as the crush strength, particle size, and size distribution, surface area, and metal contamination levels are used to assess the regenerability of the catalyst.

Efforts to develop new catalysts that last longer form the focus of current research in this area. The primary goal of this research is to create new designs to minimize deactivation and evolve proprietary chemical treatments to handle specific contaminants. Hybrid strategies involving thermal, mechanical, and chemical techniques are increasingly looked at to combat the menace. Improvements in regenerator efficiency – primarily through better temperature control and avoidance of physical damage to material (such as length-to-diameter ratio, uneven surface temperatures leading to sintering, etc.) are especially relevant to commercial practice.

Catalyst regeneration is an economically attractive option that also avoids the environmental legislation on waste disposal. Catalyst manufacturers and regenerator service providers are working together to devise new schemes to restore complete activity for reuse or secondary use of catalysts. Precise control on particle temperature and avoiding damage to catalyst hold the key for successful regeneration.

Catalysts – Selectivity and Conversion

Catalysts are highly specific compounds and have an ability to direct the reaction to yield a particular product. The ability of the catalyst to increase the rate of a particular reaction and chemisorption is the main factor in deciding the activity of a catalyst. The ability of the catalyst to direct a reaction to yield a particular product is referred to as the selectivity of the catalyst.

The reaction with same reactants but different catalyst may yield different products, which is termed as the selectivity of the catalyst, the relative activity of a catalyst with respect to a particular compound in a mixture, or the relative rate in competing reactions of a single reactant. Another term – conversion – refers to the disappearance of reactants during reaction.

See also: Adsorption, Chemisorption.

Catalyst Sintering

Overheating of catalysts leads to thermal degradation and loss of surface area resulting in decreasing catalyst activity. Sintering is normally difficult to reverse, and preventive methods are more useful than finding ways for remedies. Thus, for instance, carbon deposition and metal sintering are the major causes of deactivation of a naphtha catalytic reforming catalyst. During reforming, platinum crystallites range in size from 5 to 20 nanometers (5 to 230 nm). It is possible to redisperse the platinum by oxychlorination treatment using oxygen, a small amount of carbon tetrachloride (CCl_4), or hydrogen chloride (HCl) at 500°C (930°F). A platinum-iridium (Pt-Ir) bimetallic catalyst has also been treated in similar fashion but requires a higher treatment temperature of 550°C ($1,020^\circ\text{F}$).

The catalytic reaction takes place at the surface of the catalyst. For this reason, the catalyst must have a large area and the active component is present in the catalyst in the form of small particles, which are much less stable than large particles. A catalyst will slowly lose catalytic activity due to growth of the particle and loss of surface area.

There are two distinct mechanisms for sintering: (i) the crystallites may continuously emit and collect atoms; since the atoms will be more stable at the surface of a large particle than at the surface of a small particle, the atoms will on average migrate from the small particles to the large, or (ii) the particles may move, and when two particles come into contact, they may merge into a single, larger particle; the loss of catalytic activity due to particle growth is irreversible.

Catalysts – Solid Acid

Solid acid catalysts are environmentally friendly and highly versatile for reaction in aqueous, polar and non-polar medium as well as in gas phase. These catalysts offer non-corrosive atmosphere. A variety of industrially important reactions based on alkylation, etherification, esterification, hydrolysis, oligomerization, etc., can be carried out with these catalysts. Often, the rate and selectivity with solid acids are superior to that realized with homogeneous catalysts and, in many cases, reactions that are not feasible with homogeneous catalysts occur with solid acids. Solid acids

can be used in catalytic distillation columns and in extractive reaction modes and thus offer a number of advantages associated with capital and energy cost. Solid acids have been used for separation of close boiling isomeric/non-isomeric substances. These catalysts are used in oil refining and chemical industries. The development of new alkylation and isomerization processes using solid acids replacing liquid acids such as HF and H_2SO_4 is in progress for environmental as well as safety consideration.

Since the discovery of its strong acidity, sulfated zirconia and other sulfated metal oxides have attracted much attention as potential hydrocarbon process catalysts. These materials exhibit high acid strengths, in Hammet scale (H_0), of up to $\text{H}_0 \leq -16$. Numerous studies have been conducted on preparation, characterization, and catalytic activities of sulfated metal oxides. The usual practice of synthesis is the preparation of the hydroxide, which is then impregnated with sulfate using various precursors such as sulfuric acid (H_2SO_4), ammonium sulfate $[(\text{NH}_4)_2\text{SO}_4]$, sulfur dioxide (SO_2), hydrogen sulfide (H_2S), and sulfur trioxide (SO_3).

Heteropoly solid acids involve a large class of compounds, formed by the condensation of two or more different types of oxo-anions, containing a central atom, typically Si or P, tetrahedrally coordinated to oxygen and surrounded by oxygen-linked hexavalent 2 peripheral metal atoms.

X-ray diffraction (XRD) is used to measure the crystalline phases of the solid acids. The crystallinity of solid acids, particularly in sulfated zirconia, is an important physical property for them to be catalytically active. For instance, 600°C calcined zirconia is completely monoclinic whereas sulfated zirconia is completely tetragonal.

Due to the charge imbalance between Si^{4+} and Al^{3+} , zeolites are associated with metal ions or protons for the charge compensation. The chemical structure of bridged hydroxyls are proposed as a Si-OH group strongly influenced by a tricoordinated neighboring aluminum (Al^{3+}) atom.

The acidity in heteropolyacids is due to protons compensating the anions. In solid state, the protons are involved in formation of crystal structure of the heteropoly acids and in the protonation of more accessible terminal oxygen leading to the H_5O_2^+ species which link four neighboring heteropoly anions by forming hydrogen bonds with terminal $\text{W}=\text{O}$ oxygen. The states of protons were studied by high resolution solid state ^1H NMR. In the case of bulk hydrated heteropoly anions, it is observed by ^{17}O NMR of solid molybdophosphate that the terminal oxygens are predominant protonation sites. Heteropoly acids such as $\text{Cs}_x\text{H}_{3-x}\text{PW}_{12}\text{O}_{40}$ have a relatively large number of strong Brønsted acid sites.

Catalyst Stripping

Catalyst stripping is the introduction of steam, at a point where spent catalyst leaves the reactor, in order to strip, i.e., remove, deposits retained on the catalyst.

An efficient catalyst stripper design is one that maximizes mass transfer between the two phases (the stripping steam flowing up and the fluidized catalyst flowing down the stripper vessel). Hydrocarbon derivatives in the catalyst phase need to be replaced with steam. To enhance this mass transfer phenomenon, the stripper internals should have the following characteristics: (i) maximum surface area for mass transfer per unit volume of the stripper vessel, (ii) maximum cross-sectional area of the vessel available for catalyst and steam to flow through, (iii) maximum active volume, such that there are stagnation or dead zones, (iv) uniform distribution of catalyst and steam to avoid channeling and by-passing, (v) increased contact time and mixing between the two phases, (vi) excellent fluidization quality, (vii) plug flow conditions, and (viii) mechanically robust to withstand service.

Catalytic Cracking

The conversion of high-boiling feedstocks into lower boiling products by means of a catalyst which may be used in a fixed bed or fluid bed.

Catalytic cracking is basically the same as thermal cracking, but it differs by the use of a catalyst that is not consumed in the process and it is one of several practical applications used in a refinery that employ a catalyst to improve process efficiency. The original incentive to develop cracking processes arose from the need to increase gasoline supplies and to increase the octane number of gasoline, while maintaining yield from high-boiling stocks

using catalysts. Since cracking could virtually double the volume of gasoline from a barrel of crude oil, the purpose of cracking was wholly justified.

Most catalysts used in catalytic cracking consist of mixtures of crystalline synthetic silica-alumina, termed *zeolites*, and amorphous synthetic silica-alumina. The catalytic cracking processes, as well as most other refinery catalytic processes, produce coke which collects on the catalyst surface and diminishes its catalytic properties. The catalyst, therefore, needs to be regenerated continuously or periodically essentially by burning the coke off the catalyst at high temperatures. The method and frequency in which catalysts are regenerated are a major factor in the design of catalytic cracking units. A number of different catalytic cracking designs are currently in use in the United States, including fixed-bed reactors, moving-bed reactors, fluidized-bed reactors, and once-through units. The fluidized- and moving-bed reactors are by far the most prevalent.

An important purpose evolved from the ability of cracked gasoline to resist detonation that is the cause of knocking in automobile engines. In the early days of automobile engine development, *straight-run gasoline* had a lower end point (165°C, 330°F) than that of *cracked gasoline* (205°C, 400°F) and, furthermore, did not color when exposed to sunlight. Similar exposure caused the cracked gasoline to turn brown, and hence straight-run gasoline was regarded as the premium material.

Gasoline is now produced, for the most part, by catalytic cracking processes or by reforming processes. In catalytic cracking, the crude oil (or crude oil-derived feedstock) is fed into a reaction vessel containing a catalyst. In reforming processes, naphtha (refined or unrefined) that may have been produced by catalytic cracking of higher molecular weight feedstocks, is heated with hydrogen in the presence of a catalyst. Reforming causes a rearrangement of the structures of the molecular constituents and creates a gasoline product.

Catalytic cracking has a number of advantages over thermal cracking. Gasoline produced by catalytic cracking has a higher octane number and consists largely of *iso*-paraffins and aromatics. The *iso*-paraffins and aromatic hydrocarbon derivatives have high octane numbers and greater chemical stability than mono-olefins ($R-CH=CH_2$ or $R-CH=CH-R^1$) and diolefins ($R-CH=CH-CH=CH_2$ or $R-CH=CH(CH_2)_nCH=CH-R^1$). The olefins and diolefins are present in much greater quantities in gasoline produced by thermal cracking processes. Furthermore, substantial quantities of olefin gases and smaller quantities of methane (CH_4), ethane (CH_3CH_3), and ethylene ($CH_2=CH_2$) are produced by catalytic cracking. The olefin gases are suitable for polymer gasoline manufacture.

Sulfur compounds are changed in such a way that the sulfur content of gasoline produced by catalytic cracking gasoline is lower than the sulfur content of gasoline produced by thermal cracking. Catalytic cracking produces less residuum and more of the useful gas oil constituents than thermal cracking. Finally, the process has considerable flexibility, permitting the manufacture of both motor gasoline and aviation gasoline and a variation in the gas oil production to meet changes in the fuel oil market.

The feedstocks for catalytic cracking can be any one (or blends) of the following: (i) straight-run gas oil, (ii) vacuum gas oil, (iii) atmospheric residuum, and (iv) vacuum residuum. If blends of the above feedstocks are employed, compatibility of the constituents of the blends must be assured under read to conditions or excessive coke will be laid down on to the catalyst. In addition, there are several pretreatment options for the feedstocks for catalytic cracking units and these are (i) deasphalting to prevent excessive coking on catalyst surfaces, (ii) demetallation, i.e., removal of nickel, vanadium, and iron to prevent catalyst deactivation, (iii) use of a short residence time as a means of preparing the feedstock, and (iv) hydrotreating or mild hydrocracking to prevent excessive coking in the fluid catalytic cracking unit.

In addition, the goal is to reduce the sulfur content of the naphtha and there is a number of process options for reducing the sulfur level in fluid catalytic cracker naphtha; the two options that are generating the most interest are (i) hydrotreat the feedstock to the catalytic cracking unit; and (ii) hydrotreat the naphtha from the catalytic cracker.

Hydrotreating the fluid catalytic cracker feed improves naphtha yield and quality and reduces the sulfur oxide (SO_x) emissions from the catalytic cracker unit, but it is typically a high-pressure process and, furthermore, manipulation of feedstock sulfur alone may not be sufficient to meet future gasoline performance standards. Refineries wishing to process heavier crude oil may only have the option to desulfurize the resulting higher-sulfur naphtha. Hydrodesulfurization of catalytic cracker naphtha is a low-pressure process. Obviously, the selection of an optimum hydrotreating process option for reducing sulfur in catalytic cracker naphtha is determined by economic factors specific to a refinery and to the feedstock. Hydrotreating catalytic cracker feedstock can be very profitable for a refiner despite its large capital investment. By taking advantage of feedstock hydrotreating, margins can be optimized by considering the feedstock hydrotreater unit, the fluid catalytic cracker, and any post-catalytic cracker hydrotreater as one integrated upgrading step.

Catalytic cracking in the usual commercial process involves contacting a feedstock (usually a gas oil fraction) with a catalyst under suitable conditions of temperature, pressure, and residence time. By this means, a substantial part (>50%) of the feedstock is converted into gasoline and lower boiling products, usually in a single-pass operation. However, during the cracking reaction, carbonaceous material is deposited on the catalyst, which markedly reduces its activity, and removal of the deposit is very necessary. The carbonaceous deposit arises from the thermal decomposition of high molecular weight polar species in the feedstock. Removal of the deposit from the catalyst is usually accomplished by burning in the presence of air until catalyst activity is reestablished.

The reactions that occur during catalytic cracking are complex, but there is a measure of predictability now that catalyst activity is better understood. The major catalytic cracking reaction exhibited by paraffins is carbon-carbon bond scission into a lower-boiling paraffin derivative and an olefin. Bond rupture occurs at certain definite locations on the paraffin molecule, rather than randomly as in thermal cracking. For example, paraffins tend to crack toward the center of the molecule, the long chains cracking in several places simultaneously. Normal paraffins usually crack at carbon-carbon bonds or still nearer the center of the molecule. On the other hand, iso-paraffins tend to rupture between carbon atoms that are adjacent to a tertiary carbon atom. In either case, catalytic cracking tends to yield products containing three or four carbon atoms rather than the one- or two-carbon atom molecules produced in thermal cracking.

As in thermal cracking, high molecular weight species usually crack more readily than small molecules. However, paraffins having more than six carbon atoms may also undergo rearrangement of their carbon skeletons before cracking, and a minor amount of *dehydrocyclization* also occurs, yielding aromatics and hydrogen.

Olefins are the most reactive class of hydrocarbon derivatives in catalytic cracking and tend to crack from 1,000 to 10,000 times faster than in thermal processes. Severe cracking conditions destroy olefins almost completely, except for those in the low-boiling gasoline and gaseous hydrocarbon range and, as in the catalytic cracking of paraffins, *iso*-olefins crack more readily than *n*-olefins.

Olefins also tend to undergo rapid *isomerization* and yield mixtures with an equilibrium distribution of double-bond positions. In addition, the chain-branching isomerization of olefins is fairly rapid and often reaches equilibrium. These branched-chain olefins can then undergo *hydrogen transfer* reactions with naphthenes and other hydrocarbon derivatives. Other olefin reactions include *polymerization* as well as *condensation* to yield aromatic molecules, which in turn may be the precursors of coke formation.

Cycloparaffins (naphthenes) catalytically crack more readily than paraffins but not as readily as olefins. Naphthene cracking occurs by both ring and chain rupture and yields olefins and paraffins, but formation of methane and the C_2 hydrocarbon derivatives (ethane, CH_3CH_3 , ethylene, $CH_2=CH_2$, and acetylene, $CH\equiv CH$) is relatively minor if present at all.

Aromatic hydrocarbon derivatives exhibit wide variations in their susceptibility to catalytic cracking. The benzene ring is relatively inert, and condensed-ring compounds, such as naphthalene, anthracene, and phenanthrene, crack very slowly. When these aromatics crack, a substantial part of their *conversion* is reflected in the amount of coke deposited on the catalyst. Alkylbenzenes with attached groups of C_2 or larger primarily form benzene and the corresponding olefins, and heat sensitivity increases as the size of the alkyl group increases.

Catalytic Cracking Chemistry

Catalytic cracking is the thermal decomposition of crude oil constituents hydrocarbon derivatives in the presence of a catalyst.

Clay minerals form a family of crystalline aluminosilicate solids, and the acid treatment develops acidic sites by removing aluminum from the structure. The acid sites also catalyze the formation of coke, and Houdry developed a moving bed process that continuously removed the cooked beads from the reactor for regeneration by oxidation with air.

Although thermal cracking is a free radical (neutral) process, catalytic cracking is an ionic process involving carbonium ions, which are hydrocarbon ions having a positive charge on a carbon atom. The formation of carbonium ions during catalytic cracking can occur by: (i) addition of a proton from an acid catalyst to an olefin, and/or (ii) abstraction of a hydride ion (H^-) from a hydrocarbon by the acid catalyst or by another carbonium ion.

However, carbonium ions are not formed by cleavage of a carbon-carbon bond. In essence, the use of a catalyst permits alternate routes for cracking reactions, usually by lowering the free energy of activation for the reaction. The acid catalysts first used in catalytic cracking were amorphous solids composed of approximately 87% silica (SiO_2) and 13% alumina (Al_2O_3) and were designated low-alumina catalysts. However, this type of catalyst is now being replaced by crystalline aluminosilicates (zeolites) or molecular sieves.

The first catalysts used for catalytic cracking were acid-treated clays, formed into beads. In fact, clays are still employed as catalyst in some cracking processes.

Like the paraffins, naphthenes do not appear to isomerize before cracking. However, the naphthenic hydrocarbon derivatives (from C_9 upward) produce considerable amounts of aromatic hydrocarbon derivatives during catalytic cracking. Reaction schemes similar to that outlined here provide possible routes for the conversion of naphthenes to aromatics. Alkylated benzenes undergo nearly quantitative dealkylation to benzene without apparent ring degradation below 500°C (930°F). However, polymethyl benzene derivatives undergo disproportionation and isomerization with little benzene formation.

Coke formation is considered, with just cause to a malignant side reaction of normal carbenium ions. However, while chain reactions dominate events occurring on the surface, and produce the majority of products, certain less desirable bimolecular events have a finite chance of involving the same carbenium ions in a bimolecular interaction with one another. Of these reactions, most will produce a paraffin and leave carbene/carboid-type species on the surface. This carbene/carboid-type species can produce other products, but the most damaging product will be one which remains on the catalyst surface and cannot be desorbed and results in the formation of coke, or remains in a non-coke form but effectively blocks the active sites of the catalyst.

A general reaction sequence for coke formation from paraffins involves oligomerization, cyclization, and dehydrogenation of small molecules at active sites within zeolite pores:

Alkanes $\rightarrow$ alkenes

Alkenes $\rightarrow$ oligomers

Oligomers $\rightarrow$ naphthenes

Naphthenes $\rightarrow$ aromatics

Aromatics $\rightarrow$ coke

Whether or not these are the true steps to coke formation can only be surmised. The problem with this reaction sequence is that it ignores sequential reactions in favor of consecutive reactions. And it must be accepted that the chemistry leading up to coke formation is a complex process, consisting of many sequential and parallel reactions.

Catalytic Cracking Processes

Catalytic cracking is another innovation that truly belongs to the 20th century. It is the modern method for converting high-boiling crude oil fractions, such as gas oil, into gasoline and other low-boiling fractions. The several processes currently employed in catalytic cracking differ mainly in the method of catalyst handling, although there is an overlap with regard to catalyst type and the nature of the products. The catalyst, which may be an activated natural or synthetic material, is employed in bead, pellet, or microspherical form and can be used as a *fixed bed*, *moving-bed*, or *fluid-bed* configurations.

The fixed-bed process was the first to be used commercially and uses a static bed of catalyst in several reactors, which allows a continuous flow of feedstock to be maintained. Thus, the cycle of operations consists of (i) flow of feedstock through the catalyst bed, (ii) discontinuance of feedstock flow and removal of coke from the catalyst by burning, and (iii) insertion of the reactor on-stream.

The moving-bed process uses a reaction vessel in which cracking takes place and a kiln in which the spent catalyst is regenerated; catalyst movement between the vessels is provided by various means.

The fluid-bed process differs from the fixed-bed and moving-bed processes insofar as the powdered catalyst is circulated essentially as a fluid with the feedstock. The several fluid catalytic cracking processes in use differ primarily in mechanical design. Side-by-side, reactor-regenerator configuration or the reactor either above or below the regenerator is the main mechanical variation. From a flow standpoint, all fluid catalytic cracking processes contact the feedstock and any recycle streams with the finely divided catalyst in the reactor.

Feedstocks may range from naphtha to atmospheric residuum (*reduced crude*). Feed preparation (to remove *metallic constituents* and *high-molecular-weight non-volatile materials*) is usually carried out through any one of the following ways: coking, propane deasphalting, furfural extraction, vacuum distillation, viscosity breaking, thermal cracking, and hydrosulfurization.

The major process variables are temperature, pressure, catalyst-feedstock ratio (ratio of the weight of catalyst entering the reactor per hour to the weight of feedstock charged per hour), and space velocity (weight or volume of the feedstock charged per hour per weight or volume of catalyst in the reaction zone). Increased conversion can be obtained by applying higher temperature or higher pressure. Alternatively, lower space velocity and higher catalyst-feedstock ratio will also contribute to an increased conversion.

When cracking is conducted in a single stage, the more reactive hydrocarbon derivatives may be cracked, with a high conversion to gas and coke, in the reaction time necessary for reasonable conversion of the more refractory hydrocarbon derivatives. However, in a two-stage process, gas and gasoline from a short-reaction-time, high-temperature cracking operation is separated before the main cracking reactions take place in a second-stage reactor.

Catalytic Cracking – Process Parameters

The three main components of a fluid catalytic cracking unit are: (i) the reactor, (ii) the stripper, and (iii) the regenerator.

In the unit, the catalyst and the feed and product hydrocarbon derivatives are lifted up the riser pipe to the *reactor* where the predominately endothermic cracking processes take place. Since the reactions are endothermic, reaction temperature declines from bottom to top. At the top, the mixture enters a solid-gas separator, and the product vapors are led away. Cracked gases are separated and fractionated; the catalyst and residue, together with recycle oil from a second-stage fractionator, pass to the main reactor for further cracking. The products of this second-stage reaction are gas, gasoline, and gas oil streams, and recycle oil.

The coked catalyst enters the *stripper* where steam is added and unreacted-reacted hydrocarbon derivatives adsorbed on the catalyst are released. The stripped catalyst is then directed into the regenerator where air is added and the combustion of coke on the catalyst (and any hydrocarbon derivatives still adsorbed which were not stripped) occurs with the liberation of heat. Regenerator temperatures are typically 705 to 760°C (1300 to 1,400°F). Heat exchangers and the circulating catalyst capture the heat evolved during regeneration to be used in pre-heating the reactor feed to appropriate cracking temperatures (usually in the range, 495 to 550°C (925 to 1,020°F).

During operations, the entire catalyst inventory is *continually* circulated through the unit. Catalyst residence time in the riser reactor section is typically 1 to 3 seconds (with current trends to even shorter residence times), and the entire reactor-stripper-regenerator cycle is less than 10 minutes. To achieve cycle times of this order, catalyst circulation rates as high as 1 ton per second in large units are required. To withstand such movement, the catalyst must be sufficiently *robust* to withstand the operational stress.

Process temperatures are high, coke is repeatedly deposited and burned off, and the catalyst particles are moving at high speed through steel reactors and pipes. Contact between the catalyst particles and the metal walls and inter-particle contact are unavoidable. Thus, catalyst loss from the unit caused by poor attrition resistance can be a serious problem, since the quantities lost must be replaced by fresh catalyst additions to maintain constant unit performance. Catalyst manufacturers work hard to prevent inordinate losses due to attrition, and refineries keep a close watch on catalyst quality to be sure the produce conforms to their specifications. Therefore, the robustness of the catalyst is carefully monitored and controlled to a high attrition resistance that is determined by rigorous test methods that place a semi-quantitative evaluation on attrition resistance, which is generally related to breakdown with time in commercial units.

As intimated above, in some units, cracking does not always take place in the reactor and reaction often occurs in the vertical or upward sloped pipe called the *riser* (giving credence to the name *riser reactor* and *riser pipe cracking*) forming products, including coke. Pre-heated feedstock is sprayed into the base of the riser via feed nozzles where it contacts extremely hot fluidized catalyst at 1,230 to 1,400°F (665 to 760°C). The hot catalyst vaporizes the feed and catalyzes the cracking reactions that break down the high molecular weight oil into lower-boiling components including liquefied petroleum oil gas, constituents, gasoline, and diesel fuel. The catalyst-hydrocarbon mixture flows upward through the riser for just a few seconds, and then the mixture is separated via cyclones. The catalyst-free hydrocarbon derivatives are routed to a main fractionator for separation into fuel gas, propane and butanes, gasoline, low-boiling low density cycle oils used in diesel fuel and jet fuel, and heavy fuel oil.

The primary variables available to the operation of fluid catalytic cracking units for maximum unit conversion for a given feedstock quality include catalytic variables such as: (i) catalyst activity and (ii) catalyst design, which includes availability of cracking sites and the presence of carbon on the regenerated catalyst.

The equilibrium catalyst activity, as measured by a microactivity test (MAT), is a measure of the availability of zeolite and active matrix cracking sites for conversion. Therefore, an increase in the unit activity can effect an increase in conversion, and activity is increased by one, or a combination of (i) increased fresh catalyst addition rate, (ii) increased fresh catalyst zeolite activity, (iii) increased fresh catalyst matrix activity, (iv) addition of catalyst additives to trap or passivate the deleterious effects of feed nitrogen, alkalis (i.e., calcium and sodium), vanadium, and other feed metal contaminants, and (v) increased fresh catalyst matrix surface area to trap or remove feedstock contaminants.

In general, a two-digit increase in the activity as determined by the microactivity test activity appears to coincide with a 1% absolute increase in conversion. The increased matrix surface area improves conversion by providing more amorphous sites for cracking high boiling range compounds in the feedstock which cannot be cracked by the zeolite. Increased zeolite, on the other hand, provides the necessary acid cracking sites for selectively decomposing the amorphous cracked high boiling compounds and lower-boiling products.

In addition to zeolite and matrix activity, many of the physical and chemical properties of the catalyst (i.e., catalyst design) contribute to increased conversion through selectivity differences. These include zeolite type, pore size distribution, relative matrix to total surface area, and chemical composition.

Increasing the concentration of catalyst in the reactor, often referred to as cat/oil ratio, will increase the availability of cracking for maximum conversion, assuming the unit is not already operating at a catalyst circulation limit. This can be achieved by increasing reactor heat load or switching to a lower coke selective (i.e., lower delta coke) catalyst. Reactor heat load can be raised by increased reactor temperature or lower feed preheat temperature. This, in turn, increases the cat/oil ratio to maintain the unit in heat balance.

The lower the *carbon on regenerated catalyst*, the higher the availability of cracking sites since less coke is blocking acid cracking sites. The carbon on the regenerated catalyst is reduced by increasing regeneration efficiency through the use of carbon monoxide oxidation promoters. Carbon on the regenerated catalyst can also be reduced by more efficient air and spent catalyst contact. Increased regenerator bed levels also reduce the amount of carbon on the regenerated catalyst through increased residence time, but this must be traded off with reduced dilute phase disengager residence time and the possibility for increased catalyst losses.

There are also process variables that include (i) pressure, (ii) reaction time, and (iii) reactor temperature. Higher conversion and coke yield are thermodynamically favored by higher *pressure*. However, pressure is usually varied over a very narrow range due to limited air blower horsepower. Conversion is not significantly affected by unit pressure since a substantial increase in pressure is required to significantly increase conversion.

An increase in *reaction time* available for cracking also increases conversion. Fresh feed rate, riser steam rate, recycle rate, and pressure are the primary operating variables which affect reaction time for a given unit configuration. Conversion varies inversely with these stream rates due to limited reactor size available for cracking. Conversion has been increased by a decrease in rate in injection of fresh feedstock. Under these circumstances, over-cracking of gasoline to liquefied crude oil gas and to and dry gas may occur due to the increase in reactor residence time. One approach to offset any potential gasoline over-cracking is to add additional riser steam to lower hydrocarbon partial pressure for more selective cracking. Alternatively, an operator may choose to lower reactor pressure or increase the recycle rate to decrease residence time. Gasoline over-cracking may be controlled by reducing the availability of catalytic cracking sites by lowering cat/oil ratio.

Increased *reactor temperature* increases feedstock conversion, primarily through a higher rate of reaction for the endothermic cracking reaction and also through increased cat/oil ratio. A 5.5°C (10°F) increase in reactor

temperature can increase conversion by 1 to 2% absolute, but, again, this is feedstock dependent. Higher reactor temperature also increases the amount of olefins in gasoline and in the gases. This is due to the higher rate of primary cracking reactions relative to secondary hydrogen transfer reactions which saturate olefins in the gasoline boiling range and lower gasoline octane.

However, these variables are not always available for maximizing conversion since most fluid catalytic cracking units operate at an optimum conversion level corresponding to a given feed rate, feed quality, set of processing objectives, and catalyst at one or more unit constraints (e.g., wet gas compressor capacity, fractionation capacity, air blower capacity, reactor temperature, regenerator temperature, catalyst circulation). Once the optimum conversion level is found, there are very few additional degrees of freedom for changing the operating variables.

Catalytic Gas Conversion Process

The catalytic conversion of hydrogen cyanide (HCN) and carbonyl sulfide (COS) is a process used to mitigate the harmful effects of these components in gas streams by hydrolysis. Hydrolysis technology has two main fields of application, and these are (i) synthesis gas treatment upstream of an amine unit for coal or oil gasification processes, and (ii) other synthesis gas treatment where the presence of hydrogen cyanide and/or carbonyl sulfide is not acceptable to downstream processing units.

Catalytic Gasification

The concept of hydrogasification, while superficially seeming to effectively yield a gas ideal for the production of synthetic natural gas, in fact departs considerably from the idealized gasification reaction.

The ideal gasification reaction is essentially thermally neutral, so temperature control is not a problem. Further, the supply of a separate oxidant is not required, so the cost of producing pure oxygen or separating nitrogen from the off gas is avoided. Steam is the only gasification agent used, and downstream gas shift and methanation steps are eliminated.

By contrast, hydrogasification requires a hydrogen supply which is normally produced by the highly endothermic high temperature carbon-steam reaction.

Pure oxygen must be supplied to provide the heat of reaction by combustion with some of the coal. In addition, a gas shift step is required to convert the carbon monoxide to additional hydrogen, and the carbon dioxide produced is normally removed upstream of the hydrogasification unit.

The relatively pure hydrogen stream is then reacted with carbon at low-to-moderate temperatures according to the carbon-hydrogen reaction. Because this reaction is highly exothermic, some means of temperature control is required. In addition, the previously discussed problems of coal agglomeration in hydrogen atmospheres have to be countered. Consequently, both the hydrogasifier itself and the hydrogasification process in general are more complex than, say, steam/oxygen gasification followed by shift and methanation.

The integration of the hydrogen production step into the Hygas gasifier does simplify the overall process, but has resulted in a very tall and complex gasifier. In addition, the gas produced by the Hygas process is not that much better for SNG production than the off gas from the established Lurgi gasifier.

The major problem with the ideal gasification route is that the rate of methane formation at low temperatures is slow relative to other gasification reactions. At higher temperatures, methane formation is not favored thermodynamically. One means of enhancing the rate of a specific reaction is by use of catalysts. It has been known for some time that alkali metals catalyze the reaction of carbon with steam to form mainly carbon monoxide and hydrogen. Potassium catalysts promote the gas phase shift and methanation reactions. This means that the products of carbon/steam gasification, essentially carbon monoxide and hydrogen, can be converted to methane within the gasifier. A further important advantage of alkali metal catalysts is that they reduce agglomeration of caking coals.

Earlier catalyst tests showed that the potassium must be available for combination with coal acids to be effective. Potassium hydroxide (KOH), potassium carbonate (K_2CO_3), and potassium sulfide (K_2S) are suitable catalysts, whereas the salts of strong acids such as potassium chloride (KCl) and potassium sulfate (K_2SO_4) do not have an affinity for the coal and are ineffective. It was further found that concentrations of potassium carbonate of from 10 to 20% w/w of the coal result in commercially acceptable gasification rates at 700°C (1290°F), in comparison to approximately 925°C (1,695°F) without catalyst.

While catalytic methane production at low temperature is significantly greater than that obtained with conventional gasifiers, the off gas still contains significant amounts of carbon monoxide, carbon dioxide, and hydrogen, in addition to steam. As in the conventional production of pipeline gas, these substances have to be removed or converted to methane. Instead of using a gas shift and a methanation step, in catalytic gasification, the carbon monoxide and hydrogen are separated and recycled to the gasifier. This is feasible, since the methanation reaction is close to equilibrium and there is consequently no buildup of hydrogen and carbon monoxide as would occur in an uncatalyzed system.

The addition of modest quantities of certain inorganic salts, such as alkali metal salts (such as potassium carbonate, sodium carbonate, potassium sulfide, sodium sulfide, and the like) will catalyze the steam gasification of coal. Potassium carbonate also acts as a catalyst for the methanation reaction.

In this process, crushed (-8 mesh) coal is treated with an aqueous solution of the catalyst after which the feed is dried and charged (through a system of lock hoppers) to the fluidized bed gasifier at 700°C (1,300°F) and 500 psi. The bed is fluidized by a mixture of steam and recycled carbon monoxide-hydrogen. Unreacted steam is condensed, and the acid gases (CO_2 , H_2S) are removed by conventional acid gas treatment. The product (methane) is separated from the carbon monoxide and hydrogen by a cryogenic process. The solid product (which is actually a mixture of char, coal minerals, and the catalyst) is removed on a continuous basis; the majority of the catalyst is recovered and recycled.

Catalytic Oxidation Processes

Catalytic oxidation is a chemical conversion process that is used predominantly for destruction of volatile organic compounds and carbon monoxide. The process is used predominantly for destruction of volatile organic compounds and carbon monoxide. These systems operate in a temperature regime of 205 to 595°C (400 to 1,100°F) in the presence of a catalyst. Without the catalyst, the system would require higher temperatures. Typically, the catalysts used are a combination of noble metals deposited on a ceramic base in a variety of configurations (e.g., honeycomb-shaped) to enhance good surface contact.

Catalytic systems are usually classified on the basis of bed types such as fixed bed (or packed bed) and fluid bed (fluidized bed). These systems generally have a high destruction efficiency for most volatile organic compounds, resulting in the formation of carbon dioxide, water, and varying amounts of hydrogen chloride (from halogenated hydrocarbon derivatives). The presence in emissions of chemicals such as heavy metals, phosphorus, sulfur, chlorine, and most halogens in the incoming air stream act as poison to the system and can foul up the catalyst.

Thermal oxidation systems, without the use of catalysts, also involve chemical conversion (more correctly, chemical destruction) and operate at temperatures in excess of 815°C (1,500°F), or 220 to 610°C (395 to 1,100°F) higher than catalytic systems. There are many variables in treating gas streams. The precise area of application of a given process is difficult to define. Several factors must be considered, and these are (i) the types and concentration of contaminants in the gas, (ii) the degree of contaminant removal desired, (iii) the selectivity of acid gas removal required, (iv) the temperature, pressure, volume, and composition of the gas to be processed, (v) the carbon dioxide-hydrogen sulfide ratio in the gas, and (vi) the desirability of sulfur recovery due to process economics or environmental issues.

In addition to hydrogen sulfide and carbon dioxide, gas may contain other contaminants, such as mercaptans and carbonyl sulfide. The presence of these impurities may eliminate some of the sweetening processes, as some processes remove large amounts of acid gas but not to a sufficiently low concentration. However, there are those processes that are not designed to remove (or are incapable of removing) large amounts of acid gases. These processes are also capable of removing the acid gas impurities to low levels when the acid gases are there in low-to-medium concentrations in the gas.

Catalytic Reforming

Like thermal reforming, *catalytic reforming* converts low-octane gasoline into high-octane gasoline (reformate) by rearranging hydrocarbon molecules in a gasoline-boiling-range feedstock to produce other hydrocarbon derivatives having a higher antiknock quality; isomerization of paraffins, cyclization of paraffins to naphthenes, dehydrocyclization of paraffins to aromatics.

Catalytic reforming uses catalytic reactions to process primarily low octane heavy straight run (from the crude distillation unit) gasoline and naphtha into high octane aromatics (including benzene). There are four major types of reactions which occur during reforming processes, and these are (i) dehydrogenation of naphthenes to aromatics, (ii) dehydrocyclization of paraffins to aromatics, (iii) isomerization, and (iv) hydrocracking. The dehydrogenation reactions are endothermic, requiring that the hydrocarbon stream be heated between each catalyst bed. All but the hydrocracking reaction release hydrogen which can be used in the hydrotreating or hydrocracking processes. Fixed-bed or moving bed processes are utilized in a series of three to six reactors.

Operating conditions are in the ranges of 425 to 530°C, 50 to 750 psig, 0.7 to 5.0 h⁻¹ space velocity, and 3.0 to 10.0 moles of gas per mole of naphtha, gas recycle ratio, depending upon the process type and catalyst employed.

Catalytic reforming is conducted in the presence of hydrogen over hydrogenation-dehydrogenation catalysts, which may be supported on alumina or silica-alumina. Depending on the catalyst, a definite sequence of reactions takes place, involving structural changes in the charge stock.

Catalytic reformer feeds are saturated (i.e., not olefin) materials; in the majority of cases, the feed may be a straight-run naphtha, but other by-product low-octane naphtha (e.g., coker naphtha) can be processed after treatment to remove olefins and other contaminants. Hydrocarbon naphtha that contains substantial quantities of naphthenes is also a suitable feed. The process uses a precious metal catalyst (platinum supported by an alumina base) in conjunction with high temperatures to reform the paraffin and naphthene constituents into high-octane components. Sulfur is a poison to the reforming catalyst, which requires that virtually all the sulfur must be removed from the heavy naphtha through hydrotreating prior to reforming. Several different types of chemical reactions occur in the reforming reactors: paraffins are isomerized to branched chains and to a lesser extent to naphthenes, and naphthenes are converted to aromatics. Overall, the reforming reactions are endothermic. The resulting product stream (*reformate*) from catalytic reforming has an RON from 96 to 102 depending on the reactor severity and feedstock quality. The dehydrogenation reactions which convert the saturated naphthenes into unsaturated aromatics produce hydrogen, which is available for distribution to other refinery hydroprocesses.

The catalytic reforming process consists of a series of several reactors which operate at temperatures of approximately 480°C (900°F). The hydrocarbon derivatives are re-heated by direct-fired furnaces in between the subsequent reforming reactors. As a result of the high temperatures, the catalyst becomes deactivated by the formation of coke (i.e., essentially pure carbon) on the catalyst which reduces the surface area available to contact with the hydrocarbon derivatives.

Catalytic reforming is usually carried out by feeding a naphtha (after pretreating with hydrogen if necessary) and hydrogen mixture to a furnace where the mixture is heated to the desired temperatures 450 to 520°C (840 to 965°F), and then passed through fixed-bed catalytic reactors at hydrogen pressures of 100 to 1,000 psi. Normally, two (or more than one) reactors are used in series, and reheaters are located between adjoining reactors to compensate for the endothermic reactions taking place. Sometimes, as many as four or five are kept on-stream in series while one or more are being regenerated. The on-stream cycle of any one reactor may vary from several hours to many days, depending on the feedstock and reaction conditions.

The product issuing from the last catalytic reactor is cooled and sent to a high-pressure separator where the hydrogen-rich gas is split into two streams: one stream goes to recycle, and the remaining portion represents excess hydrogen available for other uses. The excess hydrogen is vented from the unit and used in hydrotreating, as a fuel, or for manufacture of chemicals (e.g., ammonia). The liquid product (reformate) is stabilized (by removal of low boiling products, often referred to as light ends) and used directly in gasoline or extracted for aromatic blending stocks for aviation gasoline.

Emissions from catalytic reforming include fugitive emissions of volatile constituents in the feed, and emissions from process heaters and boilers. As with all process heaters in the refinery, combustion of fossil fuels produces

emissions of sulfur oxides, nitrogen oxides, carbon monoxide, particulate matter, and volatile hydrocarbon derivatives.

Toluene, xylene, and benzene are toxic aromatic chemicals that are produced during the catalytic reforming process and used as feedstocks in chemical manufacturing. Due to their highly volatile nature, fugitive emissions of these chemicals are a source of their release to the environment during the reforming process. Point air sources may also arise during the process of separating these chemicals.

In a continuous reformer, some particulate and dust matter can be generated as the catalyst moves from reactor to reactor, and is subject to attrition. However, due to catalyst design, little attrition occurs, and the only outlet to the atmosphere is the regeneration vent, which is most often scrubbed with a caustic to prevent emission of hydrochloric acid (this also removes particulate matter). Emissions of carbon monoxide and hydrogen sulfide may occur during regeneration of catalyst.

Catalytic Reforming - Catalysts

The reforming catalyst is usually supplied as nickel oxide that, during start-up, is heated in a stream of inert gas, then steam. When the catalyst is near the normal operating temperature, hydrogen or a low-boiling hydrocarbon is added to reduce the nickel oxide to metallic nickel.

The high temperatures (up to 870°C, 1,600°F) and the nature of the reforming reaction require that the reforming catalyst be used inside the radiant tubes of a reforming furnace. The active agent in reforming catalyst is nickel, and normally, the reaction is controlled both by diffusion and by heat transfer. Catalyst life is limited as much by physical breakdown as by deactivation.

Sulfur is the main catalyst poison, and the catalyst poisoning is theoretically reversible with the catalyst being restored to near full activity by steaming. However, in practice, the deactivation may cause the catalyst to overheat and coke, to the point that it must be replaced. Reforming catalysts are also sensitive to poisoning by heavy metals, although these are rarely present in low-boiling hydrocarbon feedstocks and in naphtha feedstocks.

Coking deposition on the reforming catalyst and ensuing gloss of catalyst activity are the most characteristic issues that must be assessed and mitigated.

While methane-rich refinery gas streams are the most common feedstocks to hydrogen plants, there is often a requirement for a variety of reasons to process a variety of higher boiling feedstocks, such as liquefied petroleum gas and naphtha. Feedstock variations may also be inadvertent due, for example, to changes in refinery off-gas composition from another unit or because of variations in naphtha composition because of feedstock variance to the naphtha unit.

Thus, when using higher boiling feedstocks in a hydrogen plant, coke deposition on the reformer catalyst becomes a major issue. Coking is most likely in the reformer unit at the point where both temperature and hydrocarbon content are high enough. In this region, hydrocarbon derivatives crack and form coke faster than the coke is removed by reaction with steam or hydrogen, and when catalyst deactivation occurs, there is a simultaneous temperature increase with a concomitant increase in coke formation and deposition. In other zones, where the hydrocarbon-to-hydrogen ratio is lower, there is less risk of coking.

Coking depends to a large extent on the balance between catalyst activity and heat input with the more active catalysts producing higher yields of hydrogen at lower temperature thereby reducing the risk of coking. A uniform input of heat is important in this region of the reformer since any catalyst voids or variations in catalyst activity can produce localized hot spots leading to coke formation and/or reformer failure.

Coke formation results in hotspots in the reformer that increases pressure drop, and reduces feedstock (methane) conversion, leading eventually to reformer failure. Coking may be partially mitigated by increasing the steam/feedstock ratio to change the reaction conditions, but the most effective solution may be to replace the reformer catalyst with one designed for higher boiling feedstocks.

A standard steam-methane reforming catalyst uses nickel on an alpha-alumina ceramic carrier that is acidic in nature. Promotion of hydrocarbon cracking with such a catalyst leads to coke formation from higher boiling feedstocks. Some catalyst formulations use a magnesia/alumina ($\text{MgO}/\text{Al}_2\text{O}_3$) support that is less acidic than α -alumina that reduces cracking on the support and allows higher boiling feedstocks (such as liquefied petroleum gas) to be used.

Further resistance to coking can be achieved by adding an alkali promoter, typically some form of potash (KOH) to the catalyst. Besides reducing the acidity of the carrier, the promoter catalyzes the reaction of steam and carbon. While carbon continues to be formed, it is removed faster than it can build up. This approach can be used with naphtha feedstocks with boiling point up to approximately 180°C (350°F). Under the conditions in a reformer, potash is volatile and it is incorporated into the catalyst as a more complex compound that slowly hydrolyzes to release potassium hydroxide (KOH). Alkali-promoted catalyst allows the use of a wide range of feedstocks, but, in addition to possible potash migration, which can be minimized by proper design and operation, the catalyst is also somewhat less active than a conventional catalyst.

Another option to reduce coking in steam reformers is to use a *pre-reformer* in which a fixed-bed of catalyst, operating at a lower temperature, upstream of the fired reformer is used. In a pre-reformer, adiabatic steam-hydrocarbon reforming is performed outside the fired reformer in a vessel containing high nickel catalyst. The heat required for the endothermic reaction is provided by hot flue gas from the reformer convection section. Since the feed to the fired reformer is now partially reformed, the steam methane reformer can operate at an increased feed rate and produce 8 to 10% additional hydrogen at the same reformer load. An additional advantage of the pre-reformer is that it facilitates higher mixed feed preheat temperatures and maintains relatively constant operating conditions within the fired reformer regardless of variable refinery off gas feed conditions. Inlet temperatures are selected so that there is minimal risk of coking and the gas leaving the pre-reformer contains only steam, hydrogen, carbon monoxide, carbon dioxide, and methane. This allows a standard methane catalyst to be used in the fired reformer, and this approach has been used with feedstocks up to low-density kerosene. Since the gas leaving the pre-reformer poses reduced risk of coking, it can compensate to some extent for variations in catalyst activity and heat flux in the primary reformer.

Catalytic Reforming – Processes

The commercial processes available for use can be broadly classified as the moving-bed, fluid-bed, and fixed-bed types. The fluid-bed and moving-bed processes use mixed non-precious metal oxide catalysts in units equipped with separate regeneration facilities. Fixed-bed processes use predominantly platinum-containing catalysts in units equipped for cycle, occasional, or no regeneration.

There are several types of catalytic reforming process configurations that differ in the manner that they accommodate the regeneration of the reforming catalyst. Catalyst regeneration involves burning off the coke with oxygen. The semi-regenerative process is the simplest configuration but does require that the unit be shut down for catalyst regeneration in which all reactors (typically four) are regenerated. The cyclic configuration utilizes an additional swing reactor that enables one reactor at a time to be taken off-line for regeneration while the other four remain in service. The continuous catalyst regeneration (CCR) configuration is the most complex configuration and enables the catalyst to be continuously removed for regeneration and replaced after regeneration. The benefit to the more complex configurations is that operating severity may be increased as a result of higher catalyst activity but this does come at an increased capital cost for the process.

Under the high-hydrogen partial pressure conditions used in catalytic reforming processes, sulfur compounds are readily converted into hydrogen sulfide, which, unless removed, builds up to a high concentration in the recycle gas. Hydrogen sulfide is a reversible poison for platinum and causes a decrease in the catalyst dehydrogenation and dehydrocyclization activities. In the first catalytic reformers, the hydrogen sulfide was removed from the gas cycle stream by absorption in, for example, diethanolamine. Sulfur is generally removed from the feedstock by use of a conventional desulfurization over cobalt-molybdenum catalyst. An additional benefit of desulfurization of the feed to a level of <5 ppm sulfur is the elimination of hydrogen sulfide (H₂S) corrosion problems in the heaters and reactors.

The yield of gasoline of a given octane number and at given operating conditions depends on the hydrocarbon types in the feed. For example, high-naphthene stocks, which readily give aromatic gasoline, are the easiest to reform and give the highest gasoline yields. Paraffinic stocks, however, which depend on the more difficult isomerization, dehydrocyclization, and hydrocracking reactions, require more severe conditions and give lower gasoline yields than the naphthenic stocks. The end point of the feed is usually limited to approximately 190°C (375°F), partially because of increased coke deposition on the catalyst as the end point during processing at approximately 15°C

(27°F). Limiting the feed end point avoids redistillation of the product to meet the gasoline end-point specification of 205°C (400°F), maximum.

Moving-bed catalytic reforming processes employ a single, moving-catalyst-bed reactor with continuous catalyst regeneration but are no longer considered commercially practical.

The catalyst is a non-precious metal oxide mixture in bead or pellet form which is transported between reactor and regenerator by mechanical or other means. Depending upon catalyst type, typical feedstock for motor-gasoline usage has an initial boiling range of 65 to 80°C (150 and 175°F) and an end-point range of 200 to 215°C (390 and 420°F).

Catalytic Three-Phase Reactors

Catalytic three-phase reactors are of great industrial importance in the crude oil and petrochemical industries; they are also used in the manufacture of synthetic fuels. A common name for this kind of reactor is a slurry reactor or slurry phase reactor.

In the reactor, a gas phase, a liquid phase, and a solid catalyst phase coexist. Some of the reactants and/or products are in the gas phase under the prevailing conditions (temperature and pressure). The gas components diffuse through the gas-liquid interface, dissolve in the liquid, diffuse through the liquid film to the liquid bulk phase, and diffuse through the liquid film around the catalyst particle to the catalyst surface, where the chemical reaction takes place. If catalyst particles are porous, a chemical reaction and diffusion take place simultaneously in the catalyst pores – the product molecules are transported in the opposite direction.

The size of the catalyst particle is of considerable importance for catalytic three-phase reactors. Catalyst particles can be small and are suspended in the liquid phase. Catalyst particles of a size similar to those used in two-phase packed bed reactors can also be used in three-phase reactors. Small catalyst particles are mainly used in bubble columns, stirred tank reactors, and fluidized beds.

On the other hand, packed bed reactors are generally filled with much larger catalyst particles.

Catalytic Transesterification

Transesterification or alcoholysis is the process in which nonedible oil is allowed to chemically react with alcohol. In this reaction, methanol and ethanol are the most commonly used alcohols because of their low cost and availability. This reaction has been widely used to reduce the viscosity of nonedible oil and for the conversion of triglycerides into ester.

The catalyzed transesterification process can be classified into acid- and base- catalyzed processes. Depending on the nature of the catalyst phase, further, the acid or base catalyst can be divided into three subclasses such as homogeneous, heterogeneous, and enzymatic catalyst. The conversion efficiency of homogeneous-catalyzed transesterification is better when the free fatty acid derivative is less than 1 mg of KOH/g of oil. Two-step transesterification process is needed when the free fatty acid value is greater than 1 milligram of potassium hydroxide per gram (1 mg KOH/g) of oil.

The process facilitates the recovery of the high amount of mixture of fatty esters, but it requires a high amount of alcohol to prevent the production of soap, which is an unwanted reaction. Enzymes (i.e., enzymatic reaction) can be used instead of catalysts, but the lipase enzymes that are mostly used in the enzymatic reaction are expensive; thus, the high cost makes the enzymatic reaction less effective than chemical reactions, and the reaction rate is slow and the productivity is low.

The main limitations of the use of a homogeneous catalyst are soap formation during the transesterification process and expensive separation of catalyst after the process. As a result, feedstocks which have a high free fatty acid content can be readily converted by the heterogeneous catalyst and heterogeneous and enzymatic catalysts are the best catalysts for the conversion of triglycerides into methyl esters. The heterogeneous catalyst has many advantages over homogeneous catalyst which are (i) easy removal of the catalyst, (ii) reusability, and (iii) easy purification.

See also: Transesterification.

Caustic Scrubbing

Hydrogen sulfide removal with caustic scrubbing is only economical when small amounts of hydrogen sulfide are present and suitable means of disposing the spent solution are available. All of the processes incorporate the same basic chemistry:

The SulphaCheck process uses sodium nitrite (NaNO_2) as the basis for the caustic process. Gas streams with elevated oxygen levels with the Sulfa Check process will produce some nitrogen oxides (NO_x) in the gas stream.

The reaction between sodium hydroxide and carbon dioxide occurs between gas streams in a scrubbing tower and can be inhibited by operating with low residence times. Absorption of hydrogen sulfide is not affected when the process operates with short contact times since the reaction is almost instantaneous.

Sodium hydroxide and sodium nitrite are consumables in the caustic-based processes and cannot be regenerated. If the waste effluent meets standards for sulfide content and iron content, it is reclaimable as a market commodity. However, in gas streams with high concentrations of carbon dioxide, the sodium carbonate concentration will be above the reclaimable limit and the effluent must be disposed.

The use of supercritical methanol, a noncatalytic transesterification process, is a way to solve the problems with catalytic transesterification. In this, the dielectric value of methanol is lowered by heating to supercritical temperature state to make a single phase of reactants. As a result, the overall reaction is to be completed in a short duration of time. Furthermore, the noncatalytic process requires no catalyst and purification is easier than the catalytic process. In this, there is no soap formation during the process. There is a limitation associated with supercritical methanol transesterification which is the expensive cost of equipment to attain the high temperature and pressure.

See also: Gas Treating.

Caustic Treating

Because of the variety of feedstock that are used to produce biogas and bio-liquids, it is inevitable that at some stage, a feedstock mat contains sulfur derivatives. These derivatives must be removed from the (gaseous or liquid) product in order for the final product to meet sales specifications and environmental regulations.

The caustic (caustic soda, NaOH , lye, potassium hydroxide, KOH) treating process is used to upgrade a wide range of fractions from liquefied petroleum gas, diesel fuel, and heating oils and finds ready use in treating biogas and bio-liquids, such as bio-oil. As the caustic solution (and often a catalyst) mixes with the feedstock, it either extracts or converts mercaptan derivative to less obnoxious products.

The process consists of mixing an aqueous solution of caustic with a product fraction as soon as possible after the fraction is distilled (or isolated) since contact with air forms free sulfur, which is very corrosive and difficult to remove from fuel-type products (or from fuel precursors). The caustic reacts with any hydrogen sulfide present to form sodium sulfide, which is soluble in water.

However, the combination of the feedstock and mercaptan-rich caustic also forms a very stable emulsion that is difficult to separate, causing significant quantities of caustic carry-over in the product. This results in off-specification products due to haze or elevated sodium concentration and loss of caustic. In many cases, the entrained caustic is fed to processes where sodium is a poison to the catalyst. Because the emulsion is so stable, knock-out drums, sand filters, and packed vessels are not able to efficiently separate the caustic emulsion from the hydrocarbon streams.

The refining industry has historically used caustic solutions to extract or treat acidic impurities in liquid hydrocarbon streams. A number of caustic processes, both regenerative and nonregenerative, can be used to remove sulfur

compounds from fuels or from precursors to fuels. The simplest process is the use of a nonregenerative solid potassium hydroxide (KOH) bed, which is effective for removal of H_2S but not for other sulfur compounds. One of the common processes for treating hydrocarbon liquids is the use of regenerative caustic wash with sodium hydroxide (NaOH). Typically, the caustic wash is located downstream of an amine unit, which is used for bulk acid gas removal which minimizes the treating duty required by caustic wash. When acid gas quantities are small, a simple caustic wash is effective and economical. However, as the quantity of contaminants increases, the caustic wash process can be expensive due to high chemical and disposal costs.

Several organic materials may be added to caustic solutions (as promoters) to increase their solubility for mercaptan derivatives. Mercaptans can be converted to disulfides by several methods. These disulfides will remain in the sweetened hydrocarbon product. The overall sulfur content, therefore, remains unchanged. However, the sulfur leaves as a disulfide derivative (typically odorless) rather than a mercaptan. The method or combination of methods that can be used depend on the mercaptan content of the product to be treated and the specification that must be met.

Among the processes that convert (oxidize) mercaptans to disulfides, the Doctor sweetening process is the earliest process. In this process, an alkaline solution of lead oxide (usually sodium plumbite) contacts the feedstock forming lead mercaptide derivatives (soluble in the oil) with the mercaptan derivatives. The mixture is then treated with powdered sulfur (which has a high affinity for lead), and a conversion of the mercaptide into a so-called disulfide (which remains in solution in the gasoline stream) occurs. The process chemistry can be represented by the following equations:

The Merox process is used to treat end-product streams by rendering any mercaptan sulfur compounds inactive. The method involves the extraction reaction of the sour feedstock containing mercaptans (RSH) with caustic soda (NaOH) in a single, multi-stage extraction column using high efficiency trays:

After extraction, the extracted mercaptans in the form of sodium mercaptides (NaSR) are catalytically oxidized to water-insoluble disulfide oils (RSSR):

The disulfide oil is decanted and sent to fuel or to further processing in a hydrotreater. The regenerated (lean) caustic is then recirculated to the extraction column.

Cellulose

Cellulose (30 to 50% w/w of total feedstock dry matter) is a glucose polymer linked by β -1,4 glycosidic bonds. The basic building block of this linear polymer is cellubiose, which is a glucose-glucose dimer:

Cellubiose

Cellulose is an organic compound polysaccharide consisting of a linear chain of several hundred to over ten thousand linked D-glucose units and has the formula $(C_6H_{10}O_5)_n$.

Cellulose

The hydrolysis of cellulose (saccharification) produces its glucose monomers.

Cellulose is an important structural component of the primary cell wall of green plants, many forms of algae, and the oomycetes. Some species of bacteria secrete it to form biofilms. Approximately 33% of all plant matter is cellulose – the cellulose content of cotton is approximately 90% and that of wood is approximately 50% (Table C-1). On the other hand, cellulase refers to a class of enzymes produced by organisms such as fungi and bacteria that catalyze the hydrolysis of cellulose (cellulolysis).

Table C-1 Amount (% w/w) of cellulose and hemicellulose in various sources *.

Source	Cellulose	Hemicellulose
Bamboo	41-49	24-28
Cattle manure	1.6-4.7	1.4-3.3
Corn cobs	45	35
Corn stover	35	28
Grasses	25-40	35-50
Hardwood stem	40-50	24-40
Leaves	15-20	80-85
Newspaper	40-55	25-40
Nut shells	25-30	25-30
Paper	85-99	0
Rice straw	40	18
Softwood stem	45-50	25-35
Sugar cane bagasse	32-48	19-24
Sweet sorghum	27	25
Switch grass	30-51	10-50
Waste papers from chemical pulps	60-70	10-20
Wheat straw	33-40	20-25

* The wastes are listed alphabetically rather than in any other order.

Hemicellulose (20 to 40% w/w of total feedstock dry matter) is a short, highly branched polymer of five (C_5) and six-carbon (C_6) sugar derivatives. Specifically, hemicellulose contains xylose and arabinose (C_5 sugars) and galactose, glucose, and mannose (C_6 sugars). Hemicellulose is more readily hydrolyzed than cellulose because of its branched, amorphous nature, and a major product of hemicellulose hydrolysis is xylose (a C_5 sugar).

Cellulose is a potential biofuel source and compares favorably in terms of volatiles production with lignin and lignocellulose (Table C-2).

Table C-2 The ultimate and proximate analysis of cellulose, lignin, and lignocellulose.

Composition, %v/w	Cellulose	Lignin	Lignocellulose
Carbon	47.2	72.5	53.4
Hydrogen	5.8	5.4	5.4
Nitrogen	0.0	0.0	0.0
Sulfur	0.0	0.0	0.0
Oxygen	47.0	22.1	41.0
Proximate analysis, % w/w			
Moisture	4.3	2.6	9.4
Volatile matter (daf)	84.7	76.7	76.5
Fixed carbon (daf)	11.1	20.7	13.6
Ash (dry)	0.0	0.0	0.5
Note: daf = dry, ash free

Cellulosic Biomass

The source of energy and serving point is cellulosic material, usually derived from evergreen trees that contain hemicellulose (35 to 45%), lignin (20 to 30%), and extractable materials (0 to 5%).

Cellulose is the main part of the cell wall, with the elementary formula $(C_6H_{10}O_5)_n$. It is a highly linear polysaccharide and similar to hemicellulose, but the latter has a more branched structure and is more susceptible to chemical degradation than cellulose. Lignin acts like the boundaries in the cells, and gives rigidity to the cell wall. They are complex three-dimensional polymers of phenylpropane.

The cellulosic biomass contains carbon (45 to 55 % w/w), hydrogen (5 to 7 % w/w), oxygen (40 to 50 % w/w), small amounts of sulfur (0 to 0.05 % w/w), and nitrogen (0 to 1.0 % w/w). The mineral matter content is also of importance (being converted to ash during processing) for the heating value – the heating value decreases with increasing ash content.

An important distinction in the field of wood processing is made between softwood and hardwood. The different density of the woods has influence on which technology to apply in the processing, as the density may differ considerably between different types of forest.

Another important parameter is the moisture content in the wood. As trees are dependent on water to grow, there is always a high content of water in recently chopped wood. As water evaporates, considerable amounts of energy are required and less energy is available. The moisture content is therefore a major element in deciding the effective heating value (EHV). The EHV is defined as the lower heating value (LHV) subtracting the energy of evaporating the moisture content of the wood. The LHV assumes that the produced water is 100% evaporated. The water might leave the process as liquid water and not as vapor. The resulting energy content is defined as higher heating value (HHV). The LHV has been used traditionally, and serve as the definition of energy content also in this study.

At moisture content of 87%, the energy content of the wood is the same as the required energy to evaporate the moisture. The critical limit is 50 to 55% moisture; further increased moisture content above this level lowers the energy content dramatically. But the moisture content should not always decrease to below a certain limit, as very dry biomass produces a synthesis gas with less hydrogen.

The EHV can be calculated as an approximation with the following formula [kWh/kg]:

$$\text{EHV} = 5.326.01m = - [\text{kWh/kg}]$$

In this equation, m is the moisture content, calculated as the relation between mass of water and total mass of wood and water.

The HHV (MJ/kg) may be calculated to a reasonable approximation from the molecular composition:

$$\text{HHV} = 0.3491 \cdot X_C + 1.1783 \cdot X_H + 0.1005 \cdot X_S - 0.0151 \cdot X_N - 0.1034 \cdot X_O - 0.0211 \cdot X_{\text{ash}}$$

It is evident how hydrogen and carbon atoms are contributing to the heating value, and how the oxygen content is contributing negatively. It is therefore an important step in some biomass conversion routes to deoxidize the biomass in order to increase the heating value.

See also: Carbohydrates, Cellulose.

Cellulosic Ethanol

The first category of ethanol production technologies falls under the rubric of cellulosic ethanol.

Wood is made up, for the most part, of only three chemicals, cellulose, hemicellulose, and lignin. Cellulose and, to a lesser degree, hemicellulose provide the structural strength of wood. They are long chain molecules consisting of smaller linked sugar molecules. Cellulose, particularly, has extremely high tensile strength and gives to wood its largely unmatched structural properties.

Lignin serves as a binder and holds the chains of cellulose and hemicellulose together. It is a very tough and chemically resistant material, which explains how wooden objects can survive for hundreds and even thousands of years.

Both cellulose and hemicellulose may be converted into sugars, though not the same sugars. Cellulose produces six carbon sugars such as glucose. Hemicellulose splits into five carbon sugars such as xylose. Lignin, which is not sugar-based, generally constitutes a waste product in the production of cellulosic alcohol though it may be burned to provide processing heat or to generate electricity.

Cellulose and hemicellulose can be separated from lignin by exposure to solvents, generally acids, or by the action of enzymes, of which cellulase is the most frequently used. The enzymatic processes fall into the category of enzymatic hydrolysis, while those using acids are known collectively as acid hydrolysis. Acid hydrolysis technologies are further divided into two subcategories, concentrated acid hydrolysis and dilute acid hydrolysis.

Cellulosic ethanol manufacturing techniques are limited in the feedstocks they can accept, but the potential exists for integration of the process with other industrial energy producing processes. Thus:

Starch → hydrolysis → sugars → fermentation → product recovery

Lignocellulosic biomass → thermochemical conversion → pyrolysis oil + synthesis gas

Most have difficulties in processing softwoods, which tend to have a high lignin content, and, unfortunately, most wood waste comes from softwood sources. Agricultural wastes such as rice straw and corn stover are preferred, though many authorities believe dedicated energy crops such as switch grass, laurel, miscanthus, etc., will predominate as production increases.

See also: Carbohydrates, Cellulose, Cellulosic Biomass.

Cellulosic Materials

Cellulose from wood, agricultural residue, waste sulfite liquor from pulp, and paper mills must first be converted to sugar before it could be fermented. Enormous amounts of carbohydrate-containing cellulosic wastes are generated every year throughout the world ethanol production. The technology for converting this material into ethanol is available, but the stoichiometry of the process is unfavorable. Approximately two-thirds of the mass disappears during the conversion of cellulose to ethanol, most of it as carbon dioxide in the fermentation of glucose to ethanol. This amount of carbon dioxide leads to a disposal problem rather than to a raw material credit. Another problem is that the aqueous acid used to hydrolyze the cellulose in wood to glucose and other simple sugars destroys much of the sugar in the process.

Of the cellulose materials, shavings, sawdust, and straw are used for fuel in some places. They are bulky and difficult to handle, while their heat value, which depends on the amount of moisture they contain, is seldom more than from one-third to one-half that of sub-bituminous coal. Such waste matter as spent tan-bark and bagasse (crushed sugar cane), and the pulp from sugar beets is sometimes used for fuel for evaporation for steam, but owing to the large amount of moisture they contain, the heat value is low.

The conversion of cellulosic wastes proceeds via a two-step process that involves (i) hydrolysis and (ii) fermentation with the two steps operated sequentially. The hydrolysis step is the more critical and rate-determining step, since in this process, step cellulose is transformed into glucose that is made available to the microbes responsible for the ethanol fermentation.

Among the several forms of cellulose hydrolysis (saccharification), the chemical and biological types are the most commonly applied. Because the actual hydrolysis is accomplished enzymatically, the biological hydrolysis is designated as enzymatic hydrolysis. Although the use of enzymes avoids the corrosion problems and the loss of fuel product associated with acid hydrolysis, enzymes have their own drawbacks. Enzymatic hydrolysis slows as the glucose product accumulates in the reactor vessel. The end product inhibition eventually halts the hydrolysis unless some way is found to draw off the glucose as it is formed.

See also: Carbohydrates, Cellulose, Cellulosic Biomass.

Centrifugal Separation

In the process known as sedimentation, two immiscible liquids, or a liquid and a solid, differing in density, are separated by allowing them to come to equilibrium under the action of gravity, the heavier material falling with respect to the lighter material. This process may be accelerated by applying centrifugal forces to increase the rate of sedimentation; this is called centrifugal separation.

Typically, the centrifuge consists of a horizontal revolving shell or bowl, cylindroconical in form, inside which a screw conveyor of similar section rotates in the same direction at a slightly higher or lower speed. The feed pulp is admitted to the bowl through the center tube of the revolving-screw conveyor. When it leaves the feed pipe, the slurry is immediately subjected to a high centrifugal force, causing the solids to settle on the inner surface of the bowl at a rate which depends on the rotational speed employed – typically between 1,600 and 8,500 revolutions per minute (rev min^{-1}). The separated solids are conveyed by the scroll out of the liquid and discharged through outlets at the smaller end of the bowl. The solids are continuously dewatered by centrifugal force as they proceed from the liquid zone to the discharge. Excess entrained liquor drains away to the pond circumferentially through the particle bed. When the liquid reaches a predetermined level, it overflows through the discharge ports at the larger end of the bowl.

The centrifugal force depends upon the radius and speed of rotation and upon the mass of the particle. If the radius and the speed of rotation are fixed, then the controlling factor is the weight of the particle so that the heavier the particle, the greater the centrifugal force acting on it. Consequently, if two liquids, one of which is twice as dense as the other, are placed in a bowl and the bowl is rotated about a vertical axis at high speed, the centrifugal force per unit volume will be twice as great for the heavier liquid as for the lighter. The heavy liquid will therefore move to occupy the annulus at the periphery of the bowl, and it will displace the lighter liquid toward the center.

Thus, centrifugal separation method employs centrifugal acceleration (up to one million times higher than the gravitational acceleration on earth) resulting from rotation in order to separate particles in a solution, as based on differences in sedimentation. The sedimentation of particles is influenced by both particle size and density, as well as by solution density and viscosity. Also, centrifugal separation can be regarded as an extension of gravity separation, as the settling rates of particles are increased under the influence of centrifugal force. It can, however, be used to separate emulsions which are normally stable in a gravity field.

Cetane Index

The cetane index is an approximation of the cetane number calculated from the density and mid-boiling point temperature, and the ignition quality of diesel fuel can also be estimated from the following formula:

$$\text{Diesel index} = (\text{aniline point (oF)} \times \text{API gravity})100$$

The cetane index is calculated based on the fuel's density and boiling range. There are two methods used: ASTM D976 or ASTM D4737. These methods are particularly suitable for straight-run fuel, catalytically cracked stocks, and blends of the two. The correlation is best for these fuels and least satisfactory for blends containing substantial proportions of thermally cracked stocks. Neither of these standards is suitable for fuel containing pure hydrocarbons, or non-crude oil-based fuels derived from biomass. In addition, these methods take no account of cetane improvers used to raise the cetane number.

Standard test method ASTM D976 uses two variable equations to determine the calculated cetane index. Thus:

$$\text{CI}_{97} = 454.74 - 1641.416D + 774.74D^2 - 0.554B + 97.803(\log B)^2$$

D is the density at 15°C [g/mL] determined by Test Method ASTM D 1298, and B is mid-boiling temperature [°C] determined by Test Method ASTM D 86 and corrected to standard barometric pressure.

Standard test method ASTM D 4737 calculates cetane index using a four-variable equation based on diesel's low, mid, and high boiling points as well as density. Thus:

$$\text{CI}_{4737} = 45.2 + 0.0892T_{10N} + [0.131 + 0.901B]T_{50N} + [0.0523 + 0.420B]T_{90N} + 0.00049[T_{210N} - T_{290N}] + 107B + 60B^2$$

D is the density at 15°C [g/mL] determined by Test Method ASTM D 1298, B is the $[e(-3.5)(D - 0.85)]^{-1}$, $T_{10} = 10\%$ distillation temperature [°C] determined by Test Method ASTM D 86 and corrected to standard barometric pressure, $T_{10N} = T_{10} - 215$, $T_{50} = 50\%$ distillation temperature [°C] determined by Test Method ASTM D 86 and corrected to standard barometric pressure, $T_{50N} = T_{50} - 260$, $T_{90} = 90\%$ distillation temperature [°C] determined by Test Method ASTM D 86 and corrected to standard barometric pressure, $T_{90N} = T_{90} - 310$.

Cetane Number

The cetane number is a measure of the tendency of a diesel fuel to knock in a diesel engine. The scale is based upon the ignition characteristics of two hydrocarbons n-hexadecane (cetane) and 2,3,4,5,6,7,8-heptamethylnonane. Cetane has a short delay period during ignition and is assigned a cetane number of 100; heptamethylnonane has a long delay period and has been assigned a cetane number of 15. Just as the octane number is meaningful for automobile fuels, the cetane number is a means of determining the ignition quality of diesel fuels and is equivalent to the percentage by volume of cetane in the blend with heptamethylnonane, which matches the ignition quality of the test fuel (ASTM D613).

The cetane number is a measure of the ignition quality of a diesel fuel. It is often mistaken as a measure of fuel quality. Cetane number is actually a measure of a fuel's ignition delay. This is the time period between the start of injection and start of combustion (ignition) of the fuel. In a particular diesel engine, higher cetane fuels will have shorter ignition delay periods than lower cetane fuels. The cetane number should not be considered alone when evaluating diesel fuel quality. API gravity, BTU content, distillation range, sulfur content, stability, and flash point are also important. In colder weather, cloud point and low temperature filter plugging point may be critical factors.

The optical method for determining cetane number (ASTM D613) requires the use of an industry standard test engine equipped with accepted instrumentation and operated under specific conditions. In this test, the engine compression ratio is varied for the test sample and reference fuels of known cetane number to obtain a fixed ignition delay. The compression ratio of the sample is bracketed by those of two reference fuels. The cetane number of the sample fuel is determined by estimating between the two reference fuel points.

There is no benefit to using a higher cetane number fuel than is specified by the engine's manufacturer. The cetane number requirements depend on engine design, size, nature of speed and load variations, and on starting and atmospheric conditions. Increase in cetane number over values actually required does not materially improve engine performance.

Diesel fuels with a cetane number lower than minimum engine requirements can cause rough engine operation. They are more difficult to start, especially in cold weather or at high altitudes. They accelerate lube oil sludge formation. Many low cetane fuels increase engine deposits resulting in more smoke, increased exhaust emissions, and greater engine wear.

Char

Char is the solid material that remains after low molecular weight gases, volatile liquids, and volatile tar have been driven out or released from a carbonaceous material, during the initial stage of thermal decomposition, such as happens during combustion or in carbonization processes. The process may also be referred to as devolatilization.

Biochar (biomass char) is the solid material obtained from the thermochemical conversion of biomass in an oxygen-limited environment. Biochar is a stable solid that is rich in carbon and can endure in the soil for millennia. Biochar may increase soil fertility of acidic soil (low pH soil) and increase agricultural productivity.

The physical and chemical properties of biochar is determined by the properties of the feedstock and the technology used to create the biochar. The properties of biochar can be characterized in several respects, including the proximate and elemental composition, pH value, and the porosity which correlate with different biochar properties. The atomic ratios of biochar, including the atomic hydrogen-to-carbon (H/C) and the atomic oxygen-to-carbon (O/C), correlate with the biochar properties that are relevant to the organic content such as polarity and aromaticity. In the carbonization process, both the atomic hydrogen-to-carbon (H/C) and the atomic oxygen-to-carbon (O/C) decreases due to the release of functional groups which contain hydrogen and oxygen.

See also: Biochar, Charcoal and Charcoal Briquettes.

Charcoal and Charcoal Briquettes

Charcoal is the blackish residue consisting of impure carbon obtained by pyrolytically removing water and other volatile constituents from animal and vegetation substances. Charcoal is usually produced by heating wood, sugar, bone char, or other substances in the absence of oxygen. The soft, brittle, lightweight, black, porous material contains 85% to 98% W/W carbon, extractable non-volatile tar, and mineral matter.

Historically, production of wood charcoal in districts where there is an abundance of wood dates back to a very remote period, and generally consists of piling billets of wood on their ends so as to form a conical pile, openings being left at the bottom to admit air, with a central shaft to serve as a flue. The whole pile is covered with turf or moistened clay. The firing is begun at the bottom of the flue, and gradually spreads outwards and upwards. The success of the operation depends upon the rate of the combustion, but generally, wood yields approximately 25% w/w charcoal but this yield is very dependent on the type of wood.

The modern process of carbonizing wood, either in small pieces or as sawdust in cast iron retorts, is extensively practiced where wood is scarce, and also for the recovery of valuable by-products (wood spirit, pyroligneous acid, wood tar), which the process permits. The question of the temperature of the carbonization is important; charcoal produced made at 300°C (570°F) is brown, soft and friable, and readily inflames at 380°C while charcoal; made at higher temperatures, it is hard and brittle, and does not fire until heated to approximately 700°C (1,290°F).

Commercial charcoal is found in lump, briquette, or extruded forms, thus (i) lump charcoal, which is made directly from hardwood material and usually produces far less ash than briquettes, (ii) briquettes, which are produced by compressing charcoal, typically made from sawdust and other wood by-products, with a binder (usually starch) and other additives, and (iii) extruded charcoal, which is made by extruding either raw ground wood or carbonized wood into logs without the need for a binder since the heat and pressure of the extruding process hold the charcoal together (Table C-3).

Table C-3 Characteristics of charcoal briquettes.

	Lump Charcoal	Briquettes	
		Without Filler	With Filler
Ash, % w/w	3-4	8	25
Moisture, % w/w	5	5	5
Carbon, % w/w	Balance	Balance	Balance
Volatiles, % w/w	10-15	10-15	10-15
Binder, % w/w	-	10	10
Calorific value, kJ/Kg	28,000	25,000	22,000
Btu/lb	12,050	10,750	9,500

Animal charcoal or bone black is the carbonaceous residue obtained by the dry distillation of bones; it contains only approximately 10% carbon, the remainder being calcium and magnesium phosphates (80%) and other inorganic material originally present in the bones. It is generally manufactured from the residues obtained in the glue and gelatin industries.

Charcoal fines have a much lower purity than lump charcoal and, in addition to charcoal, contain fragments, mineral sand and clay picked up from the earth and the surface of the wood and its bark. The fine-powdered charcoal (produced from bark, twigs, and leaves) has higher ash content than normal wood charcoal. Most of this undesired high ash material can be separated by screening the fines and rejecting undersized material passing, say, a 2- to 4-mm screen.

Briquetting requires a binder to be mixed with the charcoal fines, a press to form the mixture into a cake or briquette which is then passed through a drying oven to cure or set it by drying out the water so that the briquette is strong enough to be used in the same burning apparatus as normal lump charcoal.

Charcoal needs the addition of a sticking or agglomerating material to enable a briquette to be formed. The binder should preferably be combustible, though a non-combustible binder effective at low concentrations can be suitable. Starch is preferred as a binder though it is usually expensive. Tar and pitch from coal distillation or from charcoal retorts have been used for special purpose briquettes, but they must be carbonized again before use to form a properly bonded briquette.

The binders which have been tried are many, and the most common effective binder is starch. Approximately 4 to 8% of starch made into paste with hot water is adequate. First, the fines are dried and screened. Undersized fines are rejected and oversized hammer-milled. This powder is blended with the starch paste and fed to the briquetting press, and the resulting briquettes are dried in a continuous oven at approximately 80°C (176°F). The starch sets through loss of water, binding the charcoal into a briquette which can be handled and burned like ordinary lump charcoal in domestic stoves and grates. Briquettes bonded with tar or pitch and subsequently carbonized in charcoal furnaces to produce a metallurgical charcoal briquette of adequate crushing strength are needed.

Charcoal fines when available in large quantities do have industrial uses such as in metallurgical and calcining operations. For example, in charcoal iron making, fine charcoal can be injected at the base of the blast furnace with the air blast. Fine charcoal is excellent for producing sinter, partially reduced iron ore, to provide a high-grade feed to the blast furnace. This is one of the best ways to use charcoal fines as the amount which can be used is not limited to a percentage of the total as is the case of injection into the base of the blast furnace. Pulverized fine and lump charcoal can be burned in rotary furnaces producing cement clinker and calcium bauxite.

Chemical Composition of Biomass

The chemical characteristics of biomass affect a variety of different processes. The chemical composition of the organic component of plant biomass is particularly important for microbial fermentation, pyrolysis, and gasification. The non-combustible constituents of biomass supplies greatly affect biomass combustion processes. The overall chemical constituents are similar for most plant materials. Plant cell walls consist of water and complex carbohydrates, particularly cellulose and hemicellulose. Lignin is a non-carbohydrate plant component, the highly cross-linked polymer “mortar” that binds the plant-cell bricks together to add to the plant’s structure as it matures. The cellulose, hemicellulose, and lignin portions of the vegetable matter in terrestrial plants are also referred to as the lignocellulosic complex. These components along with proteins, gums and resins, and ash-forming minerals make up the plant’s chemical structure.

The relative proportions of cellulose, hemicellulose, and lignin vary widely in proportion between softwoods, hardwoods, and herbaceous plants. Woody plants typically consist of approximately 50% w/w cellulose, 25% w/w hemicellulose, 25% w/w lignin, and trace amounts of ash-forming minerals. Herbaceous plants may contain approximately 40% w/w cellulose, 25% w/w hemicellulose, 15% w/w lignin, 5% w/w minerals, and 15% w/w proteins plus resins. The chemical composition of biomass feedstocks varies according to plant type but also by plant part (i.e., leaves, twigs, bark, stems, and roots). Variation in the proportion of different plant types and plant part components affects a variety of biomass conversion processes. Hardwood tree species tend to contain more hemicellulose and less lignin than softwoods. Grasses contain more volatile compounds in the form of proteins, fats, and resins than other herbaceous and woody plants.

The chemical characteristics of cellulose biomass are particularly important in combustion processes. Therefore, these characteristics are important to the decision process for choosing combustion technologies. While energy content is affected by the carbohydrate content in the plant material, the non-combustible fraction is particularly important for combustion because of operational issues associated with boiler efficiency, boiler slagging and fouling, erosion and corrosion, combustion instability, and particulate carry-over.

The amount of boiler slagging and fouling largely depends on the fusion temperature of the ash and the abundance and composition of ash-forming minerals. Slagging occurs when alkaline deposits accumulate or ash clumps together on the surfaces inside boilers. Alkalis such as sodium (Na) and potassium (K) are the primary causes of boiler slagging and typically have low melting points, reducing the ash fusion temperature. High alkalinity also causes fouling and slagging in stoker-type boilers and agglomeration in fluidized bed combustors (consumption of fluidized bed material along with biomass fuels). Typically, agricultural residue has higher alkalinity than does wood residue.

The value of pounds of alkali per million Btu (lb/MMBtu) can be used as an indicator to estimate the risk of boiler slagging and fouling problems. Research indicates that biomass fuels with alkali contents below 0.4 lb/MMBtu are not likely to cause slagging problems. Consequently, biomass feedstocks with high alkalinity are often blended with other fuels to reduce alkali concentrations to control fouling and slagging problems.

The minerals that combine to form ash have no energy value, so the HHV of a feedstock generally decreases as the ash content increases, reducing boiler efficiency. The ash content of a biomass feedstock should be analyzed to assess these impacts and estimate the amount of ash requiring disposal. Usually, clean softwood and hardwood fuels contain only trace amounts of ash-forming minerals, but cereal straws such as rice straw may have ash contents above 15% to 20%. Silica (SiO_2) is an abundant ash-forming mineral in crop residues that is abrasive, buffers acid reactions in pretreatment processes, and adds to slagging problems in boilers. Because the abundance of ash-forming minerals varies widely between woody and herbaceous plants and among plant components such as bark, leaves, and stems, full characterization of the feedstock will ensure appropriate conversion process design.

It is important to analyze the sulfur content of the feedstock to estimate the amount of sulfur oxides (SO_x) likely to occur in fuel emissions. In addition to polluting the atmosphere, sulfates form deposits on boiler convection tubes, contributing to slagging problems.

Overall, biomass has lower sulfur content and particulate emissions than coal, so biomass utilization benefits the environment by reducing the emissions of SO_x and ash associated with coal-fired boilers.

Chemical Precipitation

Chemical precipitation uses the addition of chemicals to convert a soluble component in a liquid feed into an insoluble solid material which can then be removed from the solution by filtration, flotation, or settling. The process is widely used for the removal of dissolved toxic metals as insoluble metal salts.

Chemical precipitation is also used as a pretreating technique for aqueous wastes destined for biological treatment. Such treatment can be done in either an on-site plant or publicly owned treatment works (POTW). The process can be used to remove heavy metals and toxic materials which are above the limits allowed for feed to the biological creating plant. The commonest forms of anions used to form the insoluble metal salts are hydroxides from the addition of lime (CaO) or caustic (NaOH) and sulfides from the addition of ferrous sulfide (FeS).

The metals that can be precipitated from aqueous wastes in an insoluble form include arsenic, barium, cadmium, chromium, copper, lead, mercury, nickel, selenium, silver, thallium, and zinc. It is important to note that these metals are not present as elemental metal dissolved in the wastes, but are metallic ions from soluble dissociated metal salts. They can react with appropriate anions to generate insoluble particles of precipitate. The two most generic anions for metal precipitation are hydroxides and sulfides. However, as mentioned above, other specific anions are often used when metal recovery is the objective of treatment or only a single metal is present in the waste.

Hydroxide Precipitates

Most metals can be precipitated as hydroxides or oxides at high pH. The hydroxide precipitates are formed by adding hydroxide ions from lime or caustic soda to the waste stream. Among the divalent metal ions which precipitate as hydroxides are cadmium, copper, iron, lead, mercury, nickel, tin, and zinc. Ions which precipitate as trivalent hydroxides are aluminum, chromium, bismuth, gold, iron, antimony, and titanium. Silver I, copper I, and thallium IV can also be precipitated as hydroxide derivatives.

The reason for giving the effective pH range for precipitation of different cations is that many of the metal hydroxides are amphoteric. That is, they can act as either bases or acids. The metal serves as cation in the bases and as part of the anion in the acids. In the presence of sufficiently strong bases (i.e., at high pH), the metal hydroxides may redissolve, thus eliminating the hydroxide precipitate.

Sulfide Precipitates

Compared to hydroxide derivatives, sulfide derivatives have both advantages and disadvantages as a precipitant for metals. The major advantages are that sulfides have a lower solubility in water than hydroxides and do not have a pH-sensitive minimum which gives better metals removal and avoids redissolution of metals at high pH since the sulfides are not amphoteric.

The primary disadvantages to precipitation of metals as metal sulfides are (i) the potential for forming toxic hydrogen sulfide gas upon addition of sulfide chemicals to the metal-containing waste and (ii) the possibility of leaving excessive sulfide in the effluent, which would then require posttreatment. As in all these chemical treatments, some excess reagent is required to guarantee completeness of the desired reaction. However, the disadvantages of sulfide precipitation can be effectively avoided when adding sulfide as soluble salts such as sodium sulfide or bisulfide. However, the addition must be done in a closed system with adequate ventilation, and the sulfide dosage must be carefully controlled by using a sulfide-specific ion electrode to measure free sulfide. This system is capable of maintaining a free sulfide concentration of 0.5 ppm.

Also, ferrous sulfide, which is only slightly soluble in aqueous streams, is an effective sulfide precipitant. It is soluble enough to precipitate other heavy metals, but its own solubility is low enough to maintain a low free sulfide concentration which essentially eliminates the hydrogen sulfide problem in the reaction tank and ensures a low

concentration of soluble sulfide in the effluent. Unfortunately, ferrous sulfide is unstable and must be made on-site which also requires the same precautions against hydrogen sulfide generation during its preparation.

Specific Metal Precipitates

In addition to hydroxide derivatives and sulfide derivatives, a variety of precipitation agents can be used when specific metals are required to be recovered from a waste stream.

For example, cadmium and lead can be precipitated as carbonates at near neutral pH with a large attendant saving in base over hydroxide precipitation. Sodium borohydride (NaBH_4), a strong reducing agent, can be used to precipitate a variety of metal ions as elemental metals. They form a dense sludge, which can be sent to metals recovery for recycling of the metal. Sodium borohydride is especially effective for the precious metals industry, where the product is of exceptionally high value. The use of sulfate to precipitate barium and chloride to precipitate silver are classical analytical methods. Finally, the use of phosphate as a precipitant permits iron, chromium, and aluminum to be removed selectively from mixed wastes containing lower valence metal ions.

Chemical Reaction Rates

Thermodynamics describes the energy requirements of a reaction; the speed at which it progresses is termed kinetics. It is important to be able to control the rate of chemical reactions for commercial and safety reasons. If a reaction takes too long to progress, the rate at which a product is manufactured would not be viable. Alternatively, if reactions progress too fast and 'run away' out of control, there could be dangers such as explosions. The rate at which reactions take place can be affected by the concentration of reactants, pressure, temperature, wavelength and intensity of light, size of particles of solid reactants, or the presence of catalysts (i.e., substances which alter the speed of reactions without being consumed during the reaction) or impurities.

The rate equation for a chemical reaction is an equation that links the reaction rate with concentrations or pressures of reactants and constant parameters. Typically, the reaction rate, r , is given by:

$$r = k[A]^x[B]^y$$

In this equation, $[A]$ and $[B]$ express the concentration of the species A and B, respectively (usually in moles per liter, M). The exponents x and y are the partial reactions orders and are determined experimentally – for some reactions, these exponents may not be equal to the stoichiometric coefficients. The constant k is the reaction rate constant (*rate coefficient*) of the reaction, and the value of this coefficient typically depends on the reaction parameters such as temperature.

Catalysts tend to be specific to a particular reaction or family of reactions. Thus, nickel is used to facilitate hydrogenation reactions (e.g., add hydrogen to $\text{C}=\text{C}$ double bonds) whereas platinum is used to catalyze certain oxidation reactions. Sometimes, care is needed with the purity of reactants since impurities can act as unwanted catalysts; alternatively, catalysts can be inactivated by *poisoning*.

For reactions which progress slowly at room temperature, it may be necessary to heat the mixture or add a catalyst for the reaction to occur at an economically-viable rate. For fast reactions, the mixture may need to be cooled or solvent added to dilute the reactants and hence reduce the speed of reaction to manageable proportions. In general, the rate of a chemical reaction (i) doubles for every 10°C – 18°F rise in temperature, (ii) is proportional to the concentration of reactants in solution, (iii) increases with decreased particle size for reactions involving a solid, and (iv) increases with pressure for gas phase reactions.

Chemicals Reactive with Water

Chemical that are reactive with water (water-reactive chemicals) are substances are that reactive and dangerous when wet because of a chemical reaction with water. This reaction may release a gas that is either flammable or

presents a toxic health hazard or both. In addition, the heat generated when water contacts such materials is often enough for the item to spontaneously combust and even explode. These chemicals can pose a threat to any operation in which chemicals are required to improve the process.

Examples of water-reactive chemicals are the alkali metals, the alkaline earth metals, anhydrides, carbides, hydrides, sodium hydrosulfite, and similar chemicals. An example of the chemical reaction of sodium metal with water is:

The heat generated by this reaction is generally sufficient to ignite the hydrogen gas (H_2) that is evolved in the reaction and can result in an explosion, depending on the amount and surface area of the alkali metal. Elemental potassium and cesium are particularly dangerous in this regard.

Another example of a dangerous when wet substance is aluminum phosphide (AlP) which reacts with water to release highly toxic phosphine gas, PH_3 . This chemical reaction is commercially exploited to kill moles and related pests:

Thus, it is critical that water reactive substances be stored in dry areas and kept off the floor by the use of pallets or rack storage. Dangerous when wet materials should never be stored directly beneath active water sprinklers and should be isolated by a waterproof or water-resistant barrier (e.g., plastic sheeting or a water-tight secondary container) to protect the materials from water in the event the sprinkler system is activated elsewhere in the facility.

Water-reactive chemical pose serious safety and health risks. The MSDS (material safety data sheet) will provide information about these risks as well as the precautions that should be taken when handling the material. Laboratory personnel should ensure that water-reactive materials are well-marked so that fire fighters and other personnel are aware of the danger in an emergency situation and be sure to have the correct type of fire extinguisher on hand.

Chemical Treating

Chemical treating is used to remove or change the undesirable properties associated with sulfur, nitrogen, or oxygen compound contaminants in crude oil products. Chemical treating is accomplished by either extraction or oxidation (sweetening), depending upon the product. Extraction is used to remove sulfur from the low-boiling fractions of crude oil, such as propane/propylene (PP) and butane/butylene (BB). Sweetening, though, is more effective on gasoline and middle distillate products.

A typical extraction process is Merox extraction. Merox extraction is used to remove mercaptans (organic sulfur compounds) from propane/propylene and butane/butylene streams. Propane/propylene streams may undergo amine treating before the Merox extraction to remove excess hydrogen sulfide which tends to fractionate with propane/propylene and interferes with the Merox process. A caustic prewash of the propane/propylene removes any remaining trace hydrogen prior to Merox extraction.

The propane/propylene and butane/butylene streams are passed up through the trays of an extraction tower. Caustic solution flowing down the extraction tower absorbs mercaptan from the propane/propylene and butane/butylene streams. The rich caustic is then regenerated by oxidizing the mercaptans to disulfide in the presence of aqueous Merox catalyst and the lean caustic recirculated to the extraction tower. The disulfide is insoluble in the caustic and can be separated.

Oxidation (Merox sweetening) is also used on gasoline and distillate fractions and uses a solid catalyst bed. Air and a minimum amount of alkaline caustic are injected into the hydrocarbon stream. As the hydrocarbon passes through the Merox catalyst bed, sulfur mercaptans are oxidized to disulfide. In the process, the caustic is not regenerated. Before the introduction of stricter sulfur regulations, the disulfide was allowed to remain in the gasoline

product, since it does not possess the objectionable odor properties of mercaptans; hence, the product has been sweetened.

Chemical Waste

A chemical waste is any solid, liquid, or gaseous waste material that can arise from any energy source – non-renewable or renewable – which, if improperly managed or the disposal method is inappropriate or faulty, may pose substantial hazards to human health and the environment.

More generally, chemical waste is a term and covers many types of materials but is generally recognized as a waste that is composed of harmful chemicals. Thus, by this definition, organic chemical waste is composed of harmful chemicals. The wastewater treatment industry describes sludge as a waste stream resulting from wastewater treatment. This description does not provide a physical or chemical basis for a definition but is adequate for the needs of wastewater treatment plant (WWTP) operations (i.e., anyone can distinguish between the treated effluent, which flows out of the plant, and the material that is pumped, scraped, or skimmed from the treatment units).

However, this definition of sludge, although adequate for the wastewater treatment industry, is inadequate for distinguishing between waste forms because it is qualitative and it ties the designation of sludge to its origins in wastewater treatment and, in this, two materials with identical characteristics may be defined as sludge or as liquid (i.e., treated effluent) based on facility-specific treatment processes and regulatory requirements governing the off-site discharge of the effluent. In order to develop a quantitative definition of sludge which will also help with correlating waste forms with disposal options, a simple and measurable characteristic of all three waste forms needs to be identified. One option is to define sludge on the basis of the solids content.

If the waste is an aqueous solution, the type and composition of the liquid waste depend on the source. In urban areas, the main sources are households, commercial establishments, and industries. Accurate information is needed related to the characteristics of liquid wastes in order to establish proper waste management processes to deal with them. The composition of liquid waste, also known as wastewater, is highly varied and depends principally on its source. In towns and cities, the three main sources are residential, commercial, and industrial areas. This is particularly true if the liquid waste is classed as a hazardous waste.

However, all chemical wastes are not hazardous wastes and an organic chemical waste may or may not be classed as hazardous waste. In terms of fuels from non-renewable and renewable sources, an organic chemical hazardous waste is a gaseous, liquid, or material that displays either a *hazardous characteristic* or is specifically listed by name as a hazardous waste. There are four characteristics by which chemical wastes may have to be considered as hazardous: (i) ignitability, (ii) corrosivity, (iii) reactivity, and (iv) toxicity. This type of hazardous waste must be categorized as to its identity, constituents, and hazards so that it may be safely handled and the disposal method defined.

At any stage of the management process, a chemical waste may be designated by law as a *hazardous waste*. Improper disposal of these waste streams, such as organic solvents, in the past has created hazards to human health and the need for expensive cleanup operations. Correct handling of these chemicals, as well as dispensing with many of the myths related to chemical processing, can mitigate some of the problems, especially problems related to the flammability of organic liquids, that will occur when incorrect handling is practiced.

Chemicals from Biomass

While the concept of exploiting the wide range of chemicals from biomass may appear novel, the published literature shows that large numbers of metabolites have already been identified and characterized from a wide variety of plant species (Table C-4).

Table C-4 Examples of the chemicals that can be obtained from lignocellulosic biomass.

Starter	Intermediate	Products*
Cellulose	C1	Carbon dioxide
		Ethanol Formic Acid
		Synthesis gas
		Methane
	C2	Acetic acid
		Glycol aldehyde
	C3	Glyceraldehyde
		Hydroxy acetone
		Lactic acid
	C4	Erythrose
		Maleic acid
	C5	Furfural
		Levulinic acid
	C6	Fructose
		Mannitol
		Sorbitol
Hemi-cellulose	Xylose	Pentanoic acid
		Pentanol
		Furfural
Lignin	Phenols	Alcohols
		Hydrocarbons

*Listed alphabetically.

In fact, lignocellulosic biomass can be used as a source of chemicals that have a wide range of chemical, physical, and biological properties and include phenolics, nitrogen-containing compounds, and terpenes (terpenoids) and would be suitable for production in a biorefinery (Table C-5). The variety of molecular compounds is vast. For example, in the terpene group, there are six sub-groupings of molecules with a large number of applications including use in anti-cancer drugs.

Extraction procedures can have a major impact on the availability of these chemicals, and, to ensure optimal exploitation, some of the well-established extraction procedures may need to be revised. For example, in winter rapeseed, the harvested seed is crushed and the rapeseed oil extracted mechanically. The residual meal is then treated with hexane to extract the remaining oil, before being used as feed, primarily for ruminants. Rapeseed oil components have numerous applications including use in bio-diesel, and specialty chemicals.

Table C-5 Routes for the production of chemicals in a biorefinery.

Starter	Process	Intermediate	Process	Product
Lignocellulose	Hydrolysis	Cellulose	Catalytic hydrodeoxygenation	Biofuels
			Dehydration	Furfurals
			Fermentation	Alcohols
				Hydrogen
		Hemicellulose	Aqueous phase reforming	Hydrogen
				Hydrocarbons
			Dehydration	Biofuels
				Furfurals
			Fermentation	Alcohols
				Biofuels
		Lignin	Chemical conversion	Aromatics
				Dibasic acids
				Olefins
				Phenols

However, innovative oil-extraction procedures could allow greater exploitation of protein-based metabolites in the rapeseed, which can comprise 25% or more of the rapeseed mass. Research from studies, such as the Enhance project – funded by the European Community – has demonstrated that this separation would allow products to be produced for numerous applications (see diagram) with base cellulose material and some other metabolites remaining in the residual meal.

See also: Biochemicals.

Chemisorption

Chemisorption (chemical absorption) is a type of adsorption which involves a chemical reaction between the surface and the adsorbate. New chemical bonds are generated at the surface of the adsorbent. The strong interaction between the adsorbate and the substrate surface creates new types of electronic bonds. Due to specificity, the nature of chemisorption can greatly differ, depending on the chemical identity and the surface structural properties. The bond between the adsorbate and adsorbent in chemisorption is either ionic or covalent.

Chemisorption (chemical absorption) processes are characterized by a high capability of absorbing large amounts of acid gases. They use a solution of a relatively weak base, such as monoethanolamine. The acid gas forms a weak bond with the base which can be regenerated easily. Mono- and diethanolamine derivatives are frequently used for this purpose. The amine concentration normally ranges between 15 and 30%. The gas stream is passed through the amine solution where sulfides, carbonates, and bicarbonates are formed. Diethanolamine is a favored absorbent due to its lower corrosion rate, smaller amine loss potential, fewer utility requirements, and minimal reclaiming needs. Diethanolamine also reacts reversibly with 75% of carbonyl sulfides (COS), while monoethanolamine reacts irreversibly with 95% of the carbonyl sulfide and forms a degradation product that must be disposed in an environmentally acceptable manner.

In contrast with chemisorption is physisorption which leaves the chemical species of the adsorbate and surface intact. It is conventionally accepted that the energetic threshold separating the binding energy of physisorption from that of chemisorption is approximately 0.5 eV per adsorbed species.

See also: Absorption, Adsorption, Physisorption.

Chemistry in the Aquasphere

The composition and chemistry of the aquasphere are of importance for several reasons, but primarily because of the interactions between the aquasphere and living organisms. However, chemistry in the water systems of the Earth (oceans, rivers, streams, and lakes) are not as straightforward as it may seem but, in many cases, aqueous life has had to adapt to the chemistry. In addition, the impact of human activity on the chemistry of the water systems has increased over time, with pollution from various practices significantly affecting the water systems.

The water cycle offers a description of the means by which water evaporates from the surface of the Earth, rises into the atmosphere, cools, condenses to form clouds, and falls again to the surface as precipitation. This system of the cycling of water is intimately linked with energy exchanges among the atmosphere, the ocean, and land that determine the climate of the Earth and cause much of natural climate variability. For example, approximately 75% of the energy (or heat) in the global atmosphere is transferred through the evaporation of water from the surface of the Earth. On land, water evaporates from the ground, mainly from soils, plants (through transpiration), lakes, and streams. In fact, approximately 15% v/v of the water entering the atmosphere is from evaporation from the land surfaces and evapotranspiration from plants which (i) cools the surface of the Earth, (ii) cools the lower atmosphere, and (iii) provides water to the atmosphere to form clouds.

The major chemical and physical components of the global water cycle include (i) the evaporation from the ocean and land surfaces, (ii) the transport of water vapor by the atmosphere and precipitation onto the ocean and land surfaces, (iii) the net atmospheric transport of water from land areas to ocean, and (iv) the return flow of fresh water from the land back into the ocean. The additional components of oceanic water transport are few, including the mixing of fresh water through the oceanic boundary layer, transport by ocean currents, and sea ice processes.

Other than the illegal dumping of chemicals in various water systems, a major chemical effect is the acidification of the water systems of the Earth, particularly the acidification of the oceans which is manifested by is the ongoing decrease in the pH of the oceans caused by the uptake of carbon dioxide (CO_2) from the atmosphere. Seawater is slightly basic ($\text{pH} > 7$), and ocean acidification involves a shift toward pH-neutral conditions rather than a transition to acidic conditions ($\text{pH} < 7$). Thus, dissolving carbon dioxide in water increases the hydrogen ion (H^+) concentration in the water, and thus decreases the pH of the water:

Changes in water chemistry can have extensive direct and indirect effects on organisms and the habitats of the organisms. One of the most important repercussions of increasing ocean acidity relates to the production of shells and plates out of calcium carbonate (CaCO_3). This process (calcification) is important to the biology and survival of a wide range of aqueous organisms and involves the precipitation of dissolved ions into solid calcium carbonate structures which are vulnerable to dissolution unless the surrounding water contains saturating concentrations of carbonate ions (CO_3^{2-}).

The saturation state (Ω) of seawater for a mineral is a measure of the thermodynamic potential for the mineral to form or to dissolve, and for calcium carbonate is described by the following equation:

$$\Omega = [\text{Ca}^{2+}][\text{CO}_3^{2-}]/K_{\text{sp}}$$

As represented by this equation, Ω is the product of the concentrations of the reacting ions that form the mineral (Ca^{2+} and CO_3^{2-}), divided by the product of the concentrations of those ions when the mineral is at equilibrium (K_{sp}), that is, when the mineral is neither forming nor dissolving.

Using seater as an example, a natural horizontal boundary is formed as a result of temperature, pressure, and depth (the saturation horizon). Above this saturation horizon, Ω has a value greater than 1, and CaCO_3 does not readily dissolve. Below this depth, Ω has a value less than 1, and calcium carbonate will dissolve. However, if its production rate is high enough to offset dissolution, calcium carbonate can still occur where Ω is less than 1. The carbonate compression depth occurs at the depth in the ocean where production is exceeded by dissolution.

Chemistry in the Atmosphere

The composition and chemistry of the atmosphere of the Earth is of importance for several reasons, but primarily because of the interactions between the atmosphere and living organisms. The chemistry that occurs in the atmosphere involves the chemical processes that occur in the gas and particle phases to better predict their impact on air pollution and global climate change. Gases and particles are emitted to the atmosphere, often as pollutants, and they may undergo a wide range of chemical processes because of the occurrence of a variety of chemical constituents in the atmosphere. In fact, atmospheric chemistry plays an important role in controlling climate change. As an example, aerosol particles impact climate through direct radiative forcing, by indirectly modifying clouds, and by modifying carbon uptake.

The atmosphere is the envelope of gases surrounding the Earth, and it is subdivided into regions depending on the altitude. The constituents of the atmosphere are primarily nitrogen (N_2 , 78.08% v/v), oxygen (O_2 , 20.95% w/w), and water vapor (0 to 0.25% w/w), although the concentration of water vapor (H_2O) is highly variable, especially near the surface, where volume fractions can be as high as 4% in the tropics. There are many minor constituents or trace gases such as (alphabetically rather than by abundance, which is variable) argon (Ar), carbon dioxide (CO_2), helium (He), hydrogen (H_2), krypton (Kr), methane (CH_4), neon (Ne), nitrous oxide (N_2O), ozone (O_3), and water vapor (H_2O) (Table C-6).

Table C-6 Approximate composition of the atmosphere.

Component, % v/v	Amount, % v/v
Major components:	
Nitrogen (N_2)	78.08
Oxygen (O_2)	20.95
Minor/trace components:	
Argon (Ar)	0.93
Water vapor (H_2O)	0.025*
Carbon dioxide (CO_2)	0.035
Neon (Ne)	0.018
Helium (He)	0.00052
Methane (CH_4)	0.00014
Krypton (Kr)	0.00010
Nitrous oxide (N_2O)	0.00005
Hydrogen (H_2)	0.00005
Ozone (O_3)	0.0000007

*Variable; can be as high as 4% v/v in humid areas.

In addition to the gaseous constituents, the atmosphere also contains suspended solid and liquid particles. Aerosols are particulate matter usually less than 1 micron in diameter (also called 1 micrometer which is equivalent to $1 \text{ meter} \times 10^{-6}$ in diameter, i.e., one millionth of a meter or one thousandth of a millimeter, 0.001 mm, or approximately 0.000039 of an inch) that are created by gas-to-particle reactions and are lifted from the surface by the winds. A portion of these aerosols can become centers of condensation or deposition in the growth of water and ice clouds. Cloud droplets and ice crystals are made primarily of water with some trace amounts of particles and dissolved gases. Their diameters range up to 100 micrometers. Water or ice particles larger than approximately 100 microns begin to fall because of gravity and may result in precipitation at the surface.

There are a number of critical chemistry issues that are associated with a changing atmosphere, including photochemical smog, global climate change, toxic air pollutants, acidic deposition, and stratospheric ozone depletion. Much of the anthropogenic (human) impact on the atmosphere is associated with the increasing use of fossil fuels as an energy source – for things such as heating, transportation, and electric power production. Photochemical smog/tropospheric ozone is a serious environmental problem that has been associated with burning such fuels, and the result has been the formation and deposition of acid rain.

Acid rain is formed when sulfur oxides and nitrogen oxides react with water vapor and other chemicals in the presence of sunlight to form various acidic compounds in the atmosphere. The principle source of acid rain-causing pollutants, sulfur oxides and nitrogen oxides, is from fuel combustion – specifically from fuels that contain sulfur and nitrogen:

sulfurous acid

sulfuric acid

nitrous acid

nitric acid

Two of the pollutants that are emitted are hydrocarbon derivatives (e.g., unburned fuel) and nitric oxide (NO). When these pollutants build up to sufficiently high levels, a chain reaction occurs from their interaction with sunlight

in which the NO is converted to nitrogen dioxide (NO_2) – a brown gas and at sufficiently high levels can contribute to urban haze. However, a more serious problem is that nitrogen dioxide (NO_2) can absorb sunlight and break apart to produce oxygen atoms that combine with the oxygen in the air to produce ozone (O_3), a powerful oxidizing agent, and a toxic gas.

Chemistry in the Geosphere

The geosphere (also called the land systems) constitutes the terrestrial component of the systems of the Earth and encompasses all processes and activities related to the human use of land, including, technological and organizational investments and arrangements, as well as the benefits gained from land and the unintended social and ecological outcomes of societal activities. Changes in land systems have large consequences for the local environment and human well-being and are at the same time pervasive factors of global environmental change. In more specific terms, the lithosphere refers to the minerals in the crust of the Earth whereas the term geosphere is often more broad in coverage and refers to the complex and variable mixture of minerals, organic matter, water, and air which make up the soil.

Chemistry in the geosphere is related to the chemistry of the atmosphere and the aquasphere. In the relationships between the atmosphere, the water systems, and the land systems, acid rain is the precipitation phenomena that incorporate anthropogenic acids (i.e., those acids which are the result of human activities) and other acidic materials. The deposition of acidic materials into the water systems and onto the land occurs in both wet and dry forms as rain, snow, fog, dry particles, and gases. The effect of acid rain (acid deposition) on a particular ecosystem depends largely on the sensitivity of the ecosystem to the acid deposition. There is also the ability of the ecosystem to neutralize the acid as well as the concentration and composition of acid reaction products and the amount of acid added to the system.

Trace element is a term that refers to those elements that occur at low levels in a given system. There are a variety of trace elements encountered in natural waters, some of which are the nutrients required for animal and plant life. Of these, many are essential at low levels but toxic at higher levels. This is typical for many substances in the aquatic environment, a point that must be kept in mind in judging whether a particular element is beneficial or detrimental. Some of these elements, such as lead or mercury, have such toxicological and environmental significance that they are discussed in detail in separate sections.

Some of the heavy metals are among the most harmful of the elemental pollutants. These metals include essential elements like iron as well as toxic metals like lead (Pb), cadmium (Cd), and mercury (Hg). Most of them have a tremendous affinity for sulfur and attack sulfur bonds in enzymes, thus immobilizing the enzymes. Protein carboxylic acid ($-\text{COOH}$) derivatives and amino ($-\text{NH}_2$) groups are also chemically bound by heavy metals. Cadmium, copper, lead, and mercury ions bind to cell membranes, hindering transport processes through the cell wall. Heavy metals may also precipitate phosphate compounds or catalyze their decomposition.

More specifically, the chemistry that occurs in soils is a major driver of the chemistry in the geosphere. Soils transport and move water, provide homes for thousands of bacteria and other creatures, and have many different arrangements of weathered rock and minerals. When soils and minerals weather over time, the chemical composition of soil also changes.

Ion exchange involves the movement of cations (positively charged elements like calcium, magnesium, and sodium) and anions (negatively charged elements such as chloride, and compounds such as like nitrate) through the soils. In the United States, cation exchange is much more common. On the other hand, anion exchange is the interchange between a cation in the solution of water around the soil particle, and another cation that is stuck to the clay surface. The number of cations in the soil water solution is much smaller than the number that is attached to soil particles.

The total amount of positive charges that the soil can absorb (the cation exchange capacity) impacts the speed that nutrients move through the soil profile. A soil with a low cation exchange capacity is much less fertile because it cannot hold on to many nutrients, and they usually contain less clays. If the soil has a low cation exchange capacity,

it is important to apply fertilizer in small doses so it does not infiltrate into the groundwater. Also, soil with a low cation exchange capacity is less able to hold spilt chemicals.

The soil pH is a measure of soil acidity or alkalinity. The pH can range from 1 to 14, with values 0-7 being acidic, and 7-14 being alkaline – soils usually range from 4 to 10. The pH is one of the most important properties involved in plant growth, as well as understanding how rapidly reactions occur in the soil. For example, the element iron becomes less available to plants at a higher pH, which can create iron deficiency. Crops usually prefer a pH on the order of 5.5 to 8, but the value depends on the crop.

Soil particles have the ability to capture different nutrients and ions (the process is known as sorption) in which one substance takes up or holds another. In this case, soils that have high sorption can retain environmental contaminants on the particles. Soil precipitation occurs during chemical reactions when a nutrient or chemical in the soil solution (water around soil particles) transforms into a solid which is an important aspect of soils that are salty.

Interactions occur between the soil and the organic matter in the soil – the organic matter is the material derived from the decay of plants and animals which contains many hydrogen and carbon compounds. The arrangement and formation of these compounds influence a soil's ability to handle spilt chemicals and other pollutants.

Soils that alternate between wet and dry range from aerobic (having high amounts of oxygen) to anaerobic (low amounts of oxygen) which determines how soils chemically react. Oxidation and reduction reactions occur continuously.

Chemsweet Process

The Chemsweet process is a batch process for the removal of hydrogen sulfide from gas streams. The chemicals used are a mixture of zinc oxide, zinc acetate, water, and a dispersant to keep the zinc oxide particles in suspension. When one part is mixed with five parts of water, the acetate dissolves and provides a controlled source of zinc ions that react instantaneously with the bisulfide and sulfide ions that are formed when hydrogen sulfide dissolves in water. The zinc oxide replenishes the zinc acetate:

Sweetening:

Regeneration:

Overall:

The presence of carbon dioxide in the gas stream is of little consequence as the pH of the slurry is low enough to prevent significant absorption of carbon dioxide, even when the ratio of CO₂ to H₂S is high.

The Chemsweet process can treat gas streams with a high hydrogen sulfide concentration and has been operated between pressures of 89 and 1415 psi. Mercaptan concentrations in excess of 10% of the hydrogen sulfide concentration in the gas stream can be a problem. Some of the mercaptans will react with the zinc oxide and be removed from the gas. The resulting zinc mercaptide forms a sludge and possibly cause foaming problems.

However, the process uses dispersants, and antifoam additives to stabilize the process. In addition, the spent media can be disposed of in an industrial landfill only after passing leachate tests. If the leachate contains more than 20 ppm of zinc and zinc compounds, then it must be treated as a hazardous waste.

Chinese Tallow Tree

The Chinese tallow tree (*Triadica sebifera*) is a plant native to central China. The tree is most favorably grown in warm climates with well-drained soils, with the fruit being harvested in early winter after the leaves have fallen off. The Chinese Tallow Tree is shade, sun, drought, flood, freeze, and salt-tolerant, making it a plant that is hard to control. One seed contains approximately 20% w/w oil, 24% w/w tallow, 11% w/w extracted protein, 8% w/w fibrous coat, and 37% w/w shell. The tree is a member of family that has many poisonous plants, and the seed kernel oil (as opposed to the waxy outer coating around the seed) is toxic indicating a reason for caution when the tree is (or the seeds are) harvested for use.

The tree has been cultivated as a seed-oil crop in China for at least 14 centuries. Candles, soap, cloth dressing, and fuel are made from the tallow. Chinese vegetable tallow is a solid fat that is in the outer covering of the Chinese tallow seeds. The kernels produce an oil (called stillingia oil) that is used in machine oils, as a crude lamp oil, and in making varnishes and paints. It can also be converted to charcoal, methanol, ethanol, and potentially, the oil from the seeds can be a substitute for crude oil.

The oil keeps well and probably does not need refining. Since the Chinese Tallow Tree is hard to control, making it seem as if there are no impediments to its growth and often giving it the title of an invasive species in many states, California uses the tree as a street and ornamental plant and it does not interfere with the other plant life. With some tolerance to salinity, the tallow trees could be investigated as energy crops for saline situations. The tree has the ability to reach reproductive age in as little as 3 years and to remain productive for at least 60 years. It does not seem to have a preference for disturbed areas over undisturbed areas and can grow in a variety of places, including both full sunlight and shade.

Circulating Fluidized Bed Gasifier

In a circulating fluid bed (CFB) gasifier, the turbulent bed solids are collected, separated from the gas, and returned to the bed, forming a solids circulation loop. The circulating fluidized bed can be differentiated from a bubbling fluidized bed in that there is no distinct separation between the dense solids zone and the dilute solids zone. Lower bed density can be achieved with increase in gas flow rates in excess of transport velocity of the fluidized bed particles. The residence time of the solids in the circulating fluid bed is determined by the solids circulation rate, attrition of the solids, and the collection efficiency of the solids in the cyclones.

The advantages of the circulating fluidized bed gasifiers are that they are (i) suitable for rapid reactions, (ii) high conversion rates possible with low tar and unconverted carbon, and (iii) high heat transport rates possible due to high heat capacity of bed material.

The disadvantages are (i) temperature gradients occur in the direction of the solid flow, (ii) the size of fuel particles required to determine minimum transport velocity, and (iii) high velocities may result in equipment erosion and heat exchange less efficient than bubbling fluidized bed.

Claus Process

The Claus sulfur recovery process is the most widely used technology for recovering elemental sulfur from sulfur-containing (sour) gas streams. Most of the world's sulfur is produced from the acid gases coming from gas treating. Conventional three-stage Claus plants can approach 98% sulfur recovery efficiency. However, since environmental regulations have become stricter, sulfur recovery plants are required to recover sulfur with over 99.8% efficiency. To meet these stricter regulations, the Claus process underwent various modifications and add-ons.

The add-on modifications to the Claus plant can be considered as a separate operation from the Claus process, in which case it is often called a tail gas treating process. Other sulfur recovery processes can replace the Claus process where it is uneconomic or cannot meet the required specifications. Usually, such processes are used in small-scale

plants, or where the hydrogen sulfide content of the acid gas is too low for a Claus plant or one of its modified versions.

The chemistry of the Claus process involves partial oxidation of hydrogen sulfide to sulfur dioxide and the catalytically promoted reaction of hydrogen sulfide and sulfur dioxide to produce elemental sulfur. The reactions are staged and are as follows:

Thermal stage:

Thermal and catalytic stage:

The first stage of the process converts hydrogen sulfide to sulfur dioxide and to sulfur by burning the acid-gas stream with air in the reaction furnace. This stage provides sulfur dioxide for the next catalytic phase of the reaction. Multiple catalytic stages are provided to achieve a more complete conversion of the hydrogen sulfide. Each catalytic stage consists of a gas reheater, a reactor, and a condenser. Condensers are provided after each stage to condense the sulfur vapor and separate it from the main stream. Conversion efficiencies of 94-95% can be attained with two catalytic stages, while up to 97% conversion can be attained with three catalytic stages. The effluent gas is incinerated or sent to another treating unit for tail-gas treating before it is exhausted to atmosphere.

The sulfur recovery by the Claus process depends upon such things as (i) the composition of the gas stream, (ii) the age of the catalyst, and (iii) the number of reactor stages. Typical sulfur recovery efficiencies for Claus plants are 90% to 96% for a two-stage plant and 95% to 98% for a three-stage plant. Because of equilibrium limitations and other sulfur losses, overall sulfur recovery efficiency in a Claus unit usually does not exceed 98%.

The off-gas leaving a Claus plant is referred to as tail gas and, in the past, was burned to convert the unreacted hydrogen sulfide to sulfur dioxide, before discharge to the atmosphere, which has a much higher toxic limit. However, the increasing standards of efficiency required by the pressure from environmental protection have led to the development of a large number of Claus tail gas clean-up units, based on different concepts, in order to remove the last remaining sulfur species.

The oxygen-blown Claus process was originally developed to increase capacity at existing conventional Claus plants and to increase the flame temperatures of gases having low hydrogen sulfide content. The process has also been used to provide the capacity and operating flexibility for sulfur plants where the feedstock gas stream is variable in flow and composition such as often found in refineries.

The SuperClaus process consists of a thermal stage followed by three or four catalytic reaction stages with sulfur removed between stages by condensers. The first two or three reactors are filled with standard Claus catalyst, while the last reactor is filled with the selective oxidation catalyst. In the thermal stage, the acid gas is burned with a less-than-stoichiometric amount of controlled combustion air so that the tail gas leaving the last Claus reactor typically contains 0.5 to 0.9 vol.% of hydrogen sulfide. There are two main principles applied in operating the SuperClaus process: (i) operating the Claus plant with excess hydrogen sulfide to suppress the sulfur dioxide content in the Claus tail gas, and (ii) selective oxidation of the remaining hydrogen sulfide by the process catalyst selectively converts the hydrogen sulfide in the presence of water vapor and excess oxygen to elemental sulfur.

In the Clauspol process, the Claus tail gas is contacted counter-currently with an organic solvent in a low pressure drop packed column. Hydrogen sulfide and sulfur dioxide are absorbed in the solvent and react to form liquid elemental sulfur according to the Claus reaction, which is promoted by an inexpensive dissolved catalyst. The solvent is pumped around the contactor, and the heat of reaction is removed through a heat exchanger to maintain a constant temperature above the sulfur melting point. Due to the limited solubility of sulfur in the solvent, pure liquid sulfur separates from the solvent and is recovered from settling section at the bottom of the contactor. This process allows sulfur recovery up to 99.8%, and the recovery level can be customized by adapting the size of the contactor.

Clay Minerals

The term *clay* is a type of fine-grained natural soil material that contains hydrous aluminum phyllosilicates (which are the actual clay minerals) that develop plasticity when wet. Geologic clay deposits are mostly composed of phyllosilicate minerals containing variable amounts of water trapped in the mineral structure. Clays are plastic due to particle size and geometry as well as water content, and become hard, brittle, and non-plastic upon drying or firing. Depending on the soil content in which the clay exists, clay can appear in various colors from white to dull gray or brown to deep orange-red. On the other hand, clay minerals (often simply referred to, and some investigators would state incorrectly, as *clays*) are silicate minerals, which usually contain aluminum also, and constitute one of the most significant classes of secondary minerals. Although many naturally occurring deposits include both silts and clay minerals, the latter (the clay minerals) is distinguished from other fine-grained soils by differences in size and mineralogy (Table C-7).

Table C-7: General groups of clay minerals.

Group	Description
Kaolin	Includes kaolinite, halloysite minerals, and nacrite.
	Polymorphs of $\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})$.
Smectite	Includes dioctahedral smectites such as montmorillonite, nontonite, beidellite, and trioctahedral smectites such as saponite.
Illite	Includes the clay-micas; illite is the only common mineral.
Chlorite	Includes a wide variety of similar minerals with considerable chemical variation.
Others	Includes palygorskite (also known as attapulgite and sometimes referred to as Attapulgius clay) and sepiolite.
	Clay minerals with long water channels internal to their structure.

Silt, which is a fine-grained soil that does not include clay minerals, tends to have larger particle sizes than clay minerals (Table C-8).

Table C-8 Approximate sizes of the various rock types.

Name	Diameter (millimeters)
Boulder	>256
Cobble	64 to 256
Pebble	2 to 64
Sand	1/6 to 2
Silt	1/256 to 1/6
Clay	<1/256

More specifically, clay minerals are hydrous aluminum phyllosilicate derivatives that often contain variable amounts of (alphabetically rather than by abundance) alkaline earth metals (any of the six chemical elements that comprise Group IIa of the periodic table – beryllium (Be), magnesium (Mg), calcium (Ca), strontium (Sr), barium (Ba), and radium (Ra), alkali metals iron, magnesium, as well as other cations. Clay minerals form in the presence of water and have been important to life, and many theories of abiogenesis involve clay minerals (Hillier, 1995). They are important constituents of soil, and have been useful to humans since ancient times in agriculture and manufacturing.

Weathering of rocks and soil is the primary way that clays and clay minerals form at the surface of the Earth. The weathering process involves physical disaggregation and chemical decomposition that change original minerals to

clay minerals; weathering is uneven, and many stages of breakdown may be found in the same clay sample. Factors governing rock weathering and soil formation include the initial type of rock, the ratio of water to rock, the temperature, the presence of organisms and organic material, and the amount of time. The types of clay minerals found in weathering rocks strongly control how the weathered rock behaves under various climatic conditions (such as humid-tropical, dry-tropical, and temperate conditions).

Kaolinite is found in most weathering zones and soil profiles. Montmorillonites, which are chemically more complex than kaolinites, are common in the lower parts of weathering profiles, nearer the rock, where chemistry exerts a strong control on mineralogy. Complex mixed-layer clay minerals (such as illite-smectites) are abundant in clay assemblages that develop from mica-bearing precursor rocks, such as the granite plutons that occur in temperate regions of the Northeastern United States. For example, a large component of soils formed by weathering of granites may consist of metastable muscovite, biotite, and chlorite. These minerals will alter progressively to clay minerals.

Clay minerals occur under a fairly limited range of geologic conditions. The environments of formation include soil horizons, continental and marine sediments, geothermal fields, volcanic deposits, and weathering rock formations. Most clay minerals form where rocks are in contact with water, air, or steam. Examples of these situations include weathering boulders on a hillside, sediments on sea or lake bottoms, deeply buried sediments containing pore water, and rocks in contact with water heated by magma (molten rock). All of these environments may cause the formation of clay minerals from preexisting minerals. Extensive alteration of rocks to clay minerals can produce relatively pure clay deposits that are of economic interest (for example, bentonite, primarily montmorillonite used for drilling muds and clays used in ceramics).

Clay minerals typically form over long periods as a result of the gradual chemical weathering of rocks over a period of hundreds of years, usually silicate-bearing, by low concentrations of, for example, carbonic acid (H_2CO_3). This acidic chemical usually migrates through the weathering rock after leaching through upper weathered layers. In addition to the weathering process, some clay minerals are formed through hydrothermal activity. Clay deposits are typically associated with low energy deposition environments such as large lakes and marine basins. In addition, there are two types of clay deposits: (i) primary deposits and (ii) secondary deposits. In the former deposits (primary deposits), the clays (frequently referred to as primary clays) have been formed as residual deposits in the soil and remain at the site of formation, while in the latter deposits (secondary deposits), the clays (frequently referred to as secondary clays) are clays that have been transported from their original location by water erosion and deposited in new sedimentary deposits.

Clay Treating Process

Treating process distillates by passing the distillate through materials possessing decolorizing power has been in operation for many years. For example, various clay minerals and similar materials are used to treat crude oil fractions to remove diolefins, asphaltic materials, resins, acids, and constituents that give rise to color. Distillates from pyrolysis processes can be clay-treated to remove diolefins that formed gums in liquid fuels. Other processes have now largely superseded this use of clay treatment, in particular by the use of inhibitors, which, added in small amounts to liquid fuels, prevent gums from forming.

The original method of clay treatment was to percolate a liquid fuel through a tower containing coarse clay pellets. As the clay absorbed impurities from the fuel, the clay became less effective and the clay removed from the adsorption tower periodically restored the activity of the clay and burning the absorbed material under carefully controlled conditions so as not to sinter the clay.

See also: Clay Minerals.

Climate Change

By definition, climate change is a long-term shift in weather conditions that is identified by changes in temperature, precipitation, winds, and other indicators which can involve both changes in average conditions and changes in variability, including, for example, extreme events. The physical climate system involves the atmosphere, land surfaces,

and oceans of the Earth, along with the snow and ice that are so prominent in many northern climes. These components interact with one another and with aspects of the biosphere of the Earth to determine not only the day-to-day weather, but also the long-term averages that are referred to as *climate*.

The most general definition of *climate change* is a change in the statistical properties of the climate system when considered over long periods of time, regardless of cause. Accordingly, fluctuations over periods shorter than a few decades, such as El Niño, do not represent climate change. The term is sometimes used to refer to climate change caused by human activity, as opposed to changes in climate that may have resulted as part of the natural processes of the Earth. In this sense, especially in the context of environmental policy, the term *climate change* has unfortunately and incorrectly been associated with anthropogenic (human activities) global warming as the causative factor. Within scientific journals, *global warming* refers to an increase in the surface temperature of the Earth while *climate change* is an all-inclusive term that includes global events.

The issue of global climate change is often associated with the use of fossil fuels as sources of energy. Of most concern is the increase in emissions of carbon dioxide (CO₂) due to emissions from fossil fuel combustion. Other factors, including land use, ozone depletion, animal agriculture, and deforestation, are also of concern in the roles they play – both separately and collectively – in affecting climate, microclimate, and various climate variables.

Climate change is inevitable and is already happening as a result of the current interglacial period. Contributing to this change are (i) natural effects, which include the Earth in an interglacial period and (ii) anthropogenic effects, which include the release of non-indigenous gases into the atmospheres. However, the exact contribution of each to global climate change is unknown and the blame can only be partially laid on the shoulders of interglacial period and somewhat less on anthropogenic effects.

Evidence for a significant change in the climate is substantial, but – and perhaps more interestingly – the specific reasons for this change are not fully understood, although reasonably complete global records of surface temperature are available beginning from the mid-late 19th century – the time period after the Little Ice Age when warming was occurring. In the late decades of the 20th century, the term *global warming* was in vogue and substantial government funding was available for research in this area. Within the recent decades, the cause of *global cooling* has been diminished and the term *global warming* took over. But this term did not fit the prevalent weather patterns, and it is now the cause of *global climate change* – a more convenient umbrella-like catch-all for any changes (warming or cooling) that are the result of cyclic weather patterns.

In reality, the climate of the Earth can be affected by natural factors that are external to the climate system, such as changes in volcanic activity, solar output, and the variance of the orbit of the Earth around the Sun. Of these, the two factors relevant on timescales of contemporary climate change are changes in volcanic activity and changes in solar radiation. In terms of the energy balance of the Earth, these factors primarily influence the amount of incoming energy. Volcanic eruptions are episodic and have relatively short-term effects on climate.

Moreover, there are indications of a Medieval Warming Period in which the climate was warm, or warmer than it is currently. Such a statement is more than a mere scientific curiosity and has wide significance. It is generally believed that the causative agent of the global climate change is the increased amounts of carbon dioxide in the atmosphere as compared to hundreds of years ago. The carbon dioxide is produced through the combustion of fossil fuels, and the amount in the atmosphere of times past has been deduced by determination of the amounts of carbon dioxide in ice cores. But salient facts related to the mobility of carbon dioxide in ice and snow are ignored. In addition, the temperatures of the Earth during the Medieval Warm Period could not have been due to fossil fuel consumption, and therefore, it is more than likely that this demonstrates that the warming of the earth that was initiated during the last century may have been just another natural fluctuation.

A crucial feature of the climate system is that the energy of the Sun is not distributed uniformly, but is rather most intense at the equator and weakest at the poles. This non-uniform energy distribution leads to temperature differences, which the atmosphere and ocean act to reduce by transporting heat from the warm tropics to the cold Polar Regions. This non-uniform heating and the resulting heat transport give rise to ocean currents, atmospheric circulation, evaporation, and precipitation that are ultimately experienced as weather.

Since there is little or nothing that can be done to deter climate change because of the current interglacial period when warming will occur and because there is currently no major alternative to fossil fuels, politicians and other leaders, who clearly know better, feel compelled to deny it. For exactly the same reasons, politicians do not acknowledge

the needs for preparing for peak energy – perhaps it is too far into the future that peak energy will occur, and for many politicians, looking to the future means looking to the time of the next election.

Currently, in the context of climate change, there needs to be a lesser reliance on emotion and more reliance on hard accurate and reliably unbiased science. On the other hand, publicly singling out specific researchers on any side of the discussion based on perspectives that they have expressed sends a dangerous message to all researchers.

Climate change is more of a natural hazard and arises as part of the evolution of the Earth, and the idea that there can be a one-size-fits-all global solution to address future climate change fails to deal with the real and major issue of climate and climate-related issues. There should be planning (rather than responding to the panic-laden issue related to carbon dioxide) as to the means by which future generations will deal with the effects of an interglacial period on the Earth. There is a need to uphold the principles of fair-minded examination of the evidence and allow open debate.

In spite of the emphasis on increased amounts of carbon dioxide in the atmosphere being the cause of climate change, there are several other factors that can influence the climate which have been largely ignored in favor of the carbon dioxide theory. Moreover, it is the recognition of these events that will eventually stabilize global climate change which can be widely applied to reorient policies and scientific strategies for various countries. In fact, the current information for global climate change points to global warming/climate change being influenced by the sum of all effects with no one effect (such as the anthropogenic effect) being the major contributor from a multi-component group of effects.

The Earth is constantly changing since its formation and has gone through different eras like glaciations, among others. However, these changes need thousands of years to be made visible, and the current increase in the average temperature of the Earth since the pre-industrial period is happening – provided that the measurements of past climatic temperatures are accurate and beyond reproach. Thus, the assessment that the warming trend that has occurred (somewhat erratically) over the past 100 years is very likely to have some origins in natural events – the precise contributions of natural effects and anthropogenic effects on the climate are not known, but it is more accurate to conclude that many factors continue to influence climate and whether or not human activities have become a dominant force, and are responsible for most of the warming observed, is still very much open to question.

Closed-Loop Biomass

Closed-loop biomass is any organic matter from a plant which is planted for the exclusive purpose of being used to produce energy.

The term includes crops grown, in a sustainable manner, for the purpose of optimizing their value for bioenergy and bioproduct uses. This includes annual crops such as maize and wheat, and perennial crops such as trees, shrubs, and grasses such as switch grass. However, the term does not include wood or agricultural wastes or standing timber nor does it include biomass burned in conjunction with fossil fuel (co-firing) beyond such fossil fuel required for startup and flame stabilization.

A closed-loop biomass energy system includes at least one agricultural facility that produces agricultural waste: a waste processing system operable to convert the waste into biomass. It is also a wastewater treatment system operable to treat wastewater created by the waste processing system and an energy production system operable to utilize the biomass to produce energy and provide the energy to an energy end-user.

See also: Biomass.

Coagulation

Coagulation is the term usually applied to the neutralization of surface charges on particles of colloidal or near colloidal size. These charges are of the same sign for all the particles in a given suspension and can be either positive or negative. Thus, they repel each other and hold the particles apart thereby preventing agglomeration. Destroying the

repulsions between particles by neutralizing the charges that stabilize the suspension allows the particles to approach each other closely enough to touch. They can then collect into larger aggregates which can settle effectively.

The additives that are effective for neutralizing surface charge on solid particles are highly ionic electrolytes, preferably containing ions of multiple charge. The effectiveness of trivalent ions is 10 to 100 times that of monovalent or divalent ions, as measured by coagulation time. Typical coagulation additives are acids, lime (calcium hydroxide), alum [aluminum sulfate, $\text{Al}_2(\text{SO}_4)_3$], and ferric chloride (FeCl_3) or ferric sulfate [$\text{Fe}_2(\text{SO}_4)_3$]. The additive is mixed into the wastewater with intense mixing to distribute it rapidly throughout the feed stream. This is in direct contrast with flocculation, which is enhanced by gentle mixing.

See also: Chemical Precipitation, Flocculation, Sedimentation.

Coarse Materials

The coarse material, referring to biomass, includes wood residues suitable for chipping, such as slabs, edgings, and trimmings.

See also: Biomass.

Co-Combustion

Co-combustion is the combustion of one feedstock with another and is often used as a means of disposal of waste materials.

The co-combustion of waste such as scrap tires and tire-derived fuels is another option for removal of the backlog of scrap tires in storage ready for waste disposal.

Tire rubber can be combusted together with other fossil fuels as well as biomass without the major alteration of an existing combustion facility. Energy generation using scrap tires and tire-derived fuels as a supplemental fuel to coal is of particular interest and is being practiced throughout the world.

The rationale behind the use of tire rubber as a supplemental fuel for power generation is based on the following: (i) excellent combustion characteristics and high heating value, (ii) lower cost and good availability, (iii) relatively low sulfur content, especially on a btu basis, and (iv) reducing the environmental burden and health effects of tire stock piles. The heating value of tires is on the order of 15,000 to 16,000 Btu/lb, whereas typical bituminous coal (washed) has a heating value of 12,000 to 13,000 Btu/lb. Typically, the sulfur content of scrap tires and tire-derived fuels is 1.5-2%. Considering the sulfur dioxide (SO_2) emission potential and the generated energy value of the fuel (pound SO_2 produced per million BTU generated), the result is closer to that for low-sulfur containing coals.

However, the co-combustion of tire and tire-derived fuel may alter the emission characteristics of the combustion facility. The environmental impacts and health effects of tire co-combustion need to be carefully assessed for each plant with all relevant factors taken into account, viz., the combustion process itself, combustion conditions, plant design, control equipment, and its efficiency with respect to specific trace elements, feed material properties, blend ratios, and analysis techniques.

COED/COGAS Process

The COED/COGAS process involves the flow of carbonaceous feedstock (usually coal) through four fluidized bed pyrolysis stages, each operating at a higher temperature than the preceding unit. When coal is employed as the feedstock, the temperatures of the stages are selected to be just below the maximum temperature to which the particular feed coal can be heated without agglomerating.

Typical operating temperatures are 315 to 345°C (600 to 650°F) in the first stage, 425 to 455°C (800 to 850°F) in the second stage, 540°C (1,000°F) in the third stage, and 870°C (1,600°F) in the fourth stage. However, the optimum

stage temperatures (and even the number of stages) vary depending on the properties of the feed coal and therefore on the properties of the biomass feedstock.

Heat for the process is provided by burning a portion of the product char with oxygen in the presence of steam in the fourth stage. Hot gases from this stage flow countercurrent to the char and provide the hot fluidizing medium for the intermediate pyrolysis stages. The gases leaving both the first and second stages are passed to cyclones which remove the fines, but the vapors leaving the cyclones need to be quenched in a Venturi scrubber to condense the oil, and the gases and oil are separated in a decanter. The gas is desulfurized and then steam-reformed to yield hydrogen and fuel gas; the hydrogen is returned to the process.

The oil from the decanter is dehydrated, filtered, and hydrotreated to remove nitrogen, sulfur, and oxygen (forming ammonia, hydrogen sulfide, and water, respectively) to produce a heavy synthetic crude oil (ca. 25° API). The char produced by the process is desulfurized in a shift kiln, where hydrogen is treated with the char to produce hydrogen sulfide which is then absorbed by an acceptor, such as limestone or dolomite.

The COGAS process involves the gasification of the COED char to produce a synthesis gas composed of carbon monoxide and hydrogen. The heat for the char gasification reaction is provided by the combustion of part of the char.

See also: Gasification, Gasification of Biomass.

Co-Firing

Co-firing refers to the practice of introducing biomass as a supplementary energy source in coal plants. It is a near-term, low-cost option for using woody residue. Co-firing results in a net reduction in greenhouse gases and lower emissions of sulfur dioxide and nitrogen oxides.

Biomass co-firing involves the addition of biomass as a partial substitute fuel in high efficiency coal boilers. In the process, coal and biomass are co-combusted in boilers that have been designed to burn coal. For this purpose, the existing coal power plant has to be partly reconstructed and retrofitted. Co-firing is an option to convert biomass to electricity, in an efficient and clean way, and to reduce greenhouse gas emissions of the power plant.

Over the past three decades, the process of co-firing has seen a rapid development. Many plants have been retrofitted for demonstration purposes and others have been newly built to allow for biomass co-firing. There are three different concepts for co-firing biomass in coal boilers, and these concepts are (i) direct co-firing, (ii) indirect co-firing, and (iii) parallel co-firing.

In the direct co-firing option, the biomass and the coal are combusted in the same furnace. The mills for the grinding of the fuel and the burners may be separate. This depends on the biomass used and its fuel properties. This concept is most commonly used because it is the easiest to implement and the most cost-effective.

The indirect co-firing concept involves conversion of the solid biomass to a clean fuel gas, using a biomass gasifier. The gas can be combusted in the same furnace as the coal. For this reason, it is also possible to use biomass, which, for example, is difficult to grind. The gas can be cleaned and filtered before use, to remove any impurities.

The parallel co-firing concept involves the installation of a completely separate biomass boiler for increasing the steam parameters, like pressure or temperature, in the steam system of the coal power plant. This method allows the use of a high amount of biomass.

Biomass co-firing is a good method to minimize greenhouse gases, because this process reduces emissions of net carbon dioxide, methane, sulfur oxide, and nitrogen oxide. In addition, existing coal power plants can be retrofitted with minimal (if any) reduction of boiler efficiency after adjustment to the new fuel mixture. However, biomass co-firing also faces some challenges such as (i) fuel supply, fuel handling, and fuel storage as well as (ii) a potential increase in corrosion and (iii) ash deposition.

See also: Combustion.

Cogeneration

Cogeneration is the simultaneous production of heat and electricity, commonly called combined heat and power (CHP), from a single fuel. Cogeneration is a very efficient technology to generate electricity and heat simultaneously.

Using a fuel to simultaneously generate heat and electricity with a single unit is more efficient and cost-effective than generating heat and electricity separately in two different units.

More specifically, cogeneration usually entails the use of what would otherwise be waste heat (such as an exhaust from a manufacturing plant) to produce additional energy benefit, such as to provide heat or electricity for the building in which it is operating. Cogeneration is also for the environment insofar as recycling the waste heat saves other potential pollutant-generating fuels from being burned.

Traditionally, a steam turbine is used to produce electricity, although a wood gasification/internal combustion unit can also be a cogeneration unit. Several factors affect the economic feasibility of a combined heat and power unit including wood waste disposal problems, high electricity costs, and year-round steam use. More electricity and heat are generated for a lesser amount of fuel by a combined heat and power unit than by a separate heat and power (SHP) unit.

The common challenges for all wood-fired systems are ensuring adequate fuel procurement and solving the complex fuel handling and storage issues.

See also: Combustion.

Cohesive Energy Density

The cohesive energy density is the amount of energy that is needed to completely remove the unit volume of molecules from their neighbors to infinite separation (an ideal gas). This is equal to the heat of vaporization of the compound divided by its molar volume in the condensed phase.

Thus, the cohesive energy density (c) of a liquid fuel is a numerical value that indicates the energy of vaporization in calories per cubic centimeter, and is a direct reflection of the degree of van der Waals forces holding the molecules of the liquid together and can be derived by the following expression:

$$c = (\Delta h - RT)/v_m$$

In this equation, c is the cohesive energy density, Δh is the heat of vaporization, r is the gas constant, t is the temperature, and v_m is the molar volume.

The correlation between vaporization and van der Waals forces also translates into a correlation between vaporization and solubility behavior because the same intermolecular attractive forces have to be overcome to vaporize a liquid as to dissolve it. Since the solubility of two materials is only possible when their intermolecular attractive forces are similar, one might also expect that materials with similar cohesive energy density values would be miscible.

Cold Pelletizing

A cold pelletizing process for the carbonization of solid fuel pellets involves heating the pellets to 550 to 650°C (1,020 to 1,200°F) and subsequently carbonized with sand as a heat carrier. Another process involves the conversion of process (solid) fines into pellets. In the second stage, the pellets are coated with hematite ore (Fe_2O_3) and the ore-covered pellets are then coked whereupon they are softened and sintered together to form a coherent coke. The addition of a viscous oil to the mix increases the stability of the pellets in the oven. The amount of ferric oxide (Fe_2O_3) is critical, and a definite level exists that cannot be exceeded if the pellet is to retain the shape.

Combustion

All fuels contain two combustible constituents: the volatile matter and char. As the temperature of the fuel rises, the volatile matter is released in the form of vapors or vaporized tars and oils. The spurts of flame, for example, as wood burns, are an indication of the combustion of these products.

After this process ends, the solid remnants comprise of char and inert matter. The char, which is mainly carbon, can be further combusted to produce heat and carbon dioxide. The inert matter then becomes clinker, slag, or ashes.

Fuel preparation → combustion → boiler → engine or turbine

Mass burn combustion (MBC) can use municipal solid waste (MSW) to generate electricity. This is one of the main methods of incineration and has been around for years. It is commercially available and has been optimized. The plant operates by feeding waste onto a moving grate where it is burned; the heat generated by this is used to generate steam that drives a generator to produce electricity. Burning the waste produces two types of ash: (i) bottom ash and (ii) fly ash.

Incinerator bottom ash falls through the grate for collection and is either landfilled or used in the construction industry. Fly ash, which escapes with the flue gases that are emitted to the atmosphere, can contain sufficient dioxins and metals that require cleaning. As it involves the mass burning of MSW, this has many concerns attached to it. In particular, the waste is a mixture of different materials; if these are combusted, they may have a detrimental effect on the environment. The main pollutants that result from municipal solid waste are (i) gases, (ii) metals, (iii) organic compounds, and (iv) particulate matter.

An area of environmental concern is the contents of the array of gases that are emitted from the plants. The gases contain dioxins, which are suspected of causing many health problems including cancer. Another environmental issue is the particulate matter, focusing particularly on ultra-fine particles less than ten millionths of a meter in diameter. These are often inorganic materials with metals and organic compounds on their surface.

Combustion - Chemistry

Combustion occurs, chemically, by initiation and propagation of a self-supporting exothermic reaction. The physical processes involved in combustion are principally those which involve the transport of matter and the transport of energy. The conduction of heat, the diffusion of chemical species, and the bulk flow of the gas all follow from the release of chemical energy in an exothermic reaction. Thus, combustion phenomena arise from the interaction of chemical and physical processes.

The first requirement, somewhat difficult with some feedstocks because of the molecular complexity, is that the overall stoichiometry of the reaction must always be established. For these purposes, the feedstock is usually represented by carbon which can react with oxygen in two ways, producing either carbon monoxide or carbon dioxide.

In direct combustion, the feedstock is burned (i.e., the carbon and hydrogen in the feedstock are oxidized into carbon dioxide and water) to convert the chemical energy of the feedstock into thermal energy after which the sensible heat in the products of combustion can then be converted into steam that can be external work or directly into shaft horsepower (e.g., in a gas turbine).

In fact, the combustion process actually represents a means of achieving the complete oxidation of the feedstock.

On a more formal basis, the combustion process may be simply represented as the staged oxidation of feedstock carbon to carbon dioxide with any reactions of the hydrogen in the feedstock being considered to be of secondary importance.

The stoichiometric reaction equations are quite simple, but there is a confusing variation of hypotheses related to the sequential reaction mechanism which is caused to be a great extent by the heterogeneous nature (solid and gaseous phases) of the reaction. But, for the purposes of this text, the chemistry will remain simple as shown in the above equations. Other types of combustion systems may be rate-controlled due to the onset of the Boudouard reaction.

In more general terms, the combustion of carbonaceous materials (which contain hydrogen and oxygen as well as carbon) involves a wide variety of reactions between the many reactants, intermediates, and products. The reactions occur simultaneously and consecutively (in both forward and reverse directions) and may at times approach a condition of equilibrium. Furthermore, there is a change in the physical and chemical structure of the fuel particle as it burns. Also, the characteristics and physical properties of the combustion products vary. In general, the size, shape, and chemical composition of these materials determine their beneficial reuse as a component of building materials or as a replacement to other virgin materials such as sand, gravel, or gypsum.

The beneficial use of the combustion products involves the use of or substitution of the combustion products for another product based on performance criteria. Using combustion products can generate significant environmental, economic benefits. Beneficial use includes raw feed for cement clinker, concrete, grout, flowable fill, structural fill, road base/sub-base, soil-modification, mineral filler, snow and ice traction control, blasting grit and abrasives, roofing granules, mining applications, wallboard, waste stabilization/solidification, soil amendment, and agriculture.

The complex nature of biomass as a molecular entity has resulted in the chemical explanations of the combustion process being confined to the carbon in the system and, to a much lesser extent with only passing acknowledgment of the hydrogen and other elements, but it must be recognized that the system is extremely complex and that the heteroatoms (nitrogen, oxygen, and sulfur) can exert an influence on the combustion and it is this influence that can cause serious environmental concerns.

For example, the conversion of the feedstock-bound sulfur and nitrogen (in addition to any reactions or aerial nitrogen with aerial oxygen under the prevailing conditions) to their respective oxides during combustion is a major environmental issue.

Thus:

The release of the sulfur and nitrogen from the feedstock is not as simple as represented here, and the equations are simplifications of what are, presumably, complex processes.

The sulfur dioxide that escapes into the atmosphere is either deposited locally or is converted to sulfurous and sulfuric acids by reaction with moisture in the atmosphere.

Thus:

Nitrogen oxides also contribute to the formation and occurrence of acid rain, in a manner similar to the production of acids from the sulfur oxides, yielding nitrous and nitric acids.

Thus:

In addition to causing objectionable stack emissions, the ash produced during the process and volatile inorganic material generated by thermal alteration of mineral matter in coal will adversely affect heat transfer processes by fouling the heat-absorbing and radiating surfaces and will also influence the performance of the combustion system by causing corrosion, and operating procedures must therefore provide for effective countering of all these hazards.

See also: Combustion, Combustion – Effect of Additives and Catalysts, Combustion – Environmental Aspects, Combustion – Fluidized Bed, Combustion – Fouling, Combustion – Fouling – Heat Balance, Combustion – Ignition, Combustion – Influence of Feedstock Quality, Combustion – Mechanism, Combustion – Soot Formation, Combustion – Surface Effects.

Combustion – Direct

Direct combustion is a thermochemical technique in which (in the current context) biomass is burned in open air or in the presence of excess air. In this process, the photosynthetically stored chemical energy of the biomass will be converted into gases. Generally, direct combustion is carried out inside a furnace, steam turbine, or boiler at a temperature range of 800 to 1,000°C (1,470 to 1,830°F). This process is suitable for all types of biomass, which has low moisture content (<50%).

Electricity production by direct combustion is the simplest process when dry biomass is burned in co-combustion with coal. This transformation path has the lowest impacts on the environment, but it is important to notice that in this study, the needed heat to dry the biomass comes from the recovery of flue gas. Hence, it is not accounted for in the environmental balance or the energetic balance and, in addition, this approach is likely to produce high quantities of nitrogen oxides.

Another possibility for sustainable operation of microalgae biomass in direct combustion is coal–algae cofiring which has the potential to reduce the emission of carbon dioxide by recycling the carbon dioxide from

the combustion process to microalgae cultivation. This leads to lower emission of greenhouse gases into the atmosphere.

See also: Direct Combustion.

Combustion – Effect of Additives and Catalysts

Additives may catalyze or otherwise affect combustion processes. For example, salt has long been known to be of some assistance in removing soot deposits from surfaces and the catalysis of the process in which alkali salts serve to catalyze the carbon-steam reaction to produce synthesis gas (carbon monoxide/hydrogen mixtures). This mixture may then, in turn, react to produce hydrocarbon derivatives and oxygenated materials in the presence of the multitude of trace metals that can (and do) occur in biomass and waste.

In addition to causing objectionable stack emissions, the ash and volatile inorganic material generated by thermal alteration of mineral matter in the feedstock will adversely affect heat transfer processes by fouling heat-absorbing and radiating surfaces and will also influence the performance of the combustion system by causing corrosion, and operating procedures must therefore provide for effective countering of all these hazards.

Corrosion is mainly caused by oxides of sulfur, but in certain parts of a combustion system, specifically on furnace wall tubes with metal temperature of 290 to 425°C (550 to 800°F) and superheater or reheater tubes with temperatures in the range 600 to 700°C (1,110 to 1,300°F), corrosion can be induced by tube deposits that destroy protective surface oxide coatings.

Corrosion damage that is usually ascribed to sulfur is actually caused by sulfuric acid, which is generated from organic and inorganic sulfur-bearing compounds:

Oxidation of sulfur dioxide to sulfur trioxide occurs mostly in flames where (transient) atomic oxygen species are thought to be prevalent by interactions of hydrogen atoms with oxygen:

as well as by interactions of carbon monoxide with oxygen:

The process can be catalyzed by the ferric oxides which form on boiler tube surfaces and show excellent catalytic activity for sulfur dioxide oxidation at approximately 600°C (1110°F), i.e., at temperatures which occur in the superheater section of a boiler.

The presence of water has a marked effect on combustion (by participating in various combustion reactions), and there is evidence for the existence of active centers for chain reactions involved in the further combustion of carbon monoxide and hydrogen (which would be reaction intermediates in the combustion process). It is generally assumed that moisture catalyzes the oxidation of coal.

The endothermic steam-carbon reaction is primarily responsible for cooling effects in furnaces, and the presence of moisture is believed to cause heat generation at the surface of the bed and in the combustion by virtue of the (endothermic) formation of carbon monoxide and hydrogen in the bed which then burn at the surface. On the other hand, the presence of water vapor appears to assist in the formation of carbon dioxide:

Moisture appears to play a more integral role in the combustion of hydrogen-deficient carbonaceous fuels than has been generally recognized. The carbon-steam reaction to produce carbon monoxide and hydrogen (which are then oxidized to the final products) is an important stage in the combustion sequence as is the carbon monoxide shift reaction to yield carbon dioxide and hydrogen:

Since the whole system involves reaction (and equilibria) between the fuel (i.e., carbon), water, carbon monoxide, hydrogen, and carbon dioxide, the rapid rates of the reactions render it difficult (if not impossible) to determine precisely which of the reactions are the major rate-controlling reactions. In addition, the heterogeneous nature of the system adds a further complication.

The presence of inert gases would usually be expected to dilute the reactants and therefore diminish the reaction rates; such inert materials may actually, on occasion, accelerate the reaction(s). Indeed, the addition of nitrogen to the reaction mixture can be as effective as the addition of oxygen. The nitric oxide formed in the mixture is believed to act as a catalyst:

Combustion – Environmental Aspects

The environmental aspects of combustion have been a major factor in the various processes. Large amounts of feedstocks are consumed in generating electricity, and the emissions from power stations and similar industrial sources represent a potential, and considerable, environmental hazard. These power plants emit effluents, which often are pollutants and which by mere contact with the external environment or by (generally) simple atmospheric chemical transformations, may form secondary pollutants that are more harmful than the initial effluent/pollutant.

The gaseous emissions resulting from the complete combustion of a carbonaceous feedstock are carbon dioxide and water. However, in the exhaust gases from any practical device, there will be, in addition to these compounds, carbon monoxide (CO), sulfur oxides (SO_x), nitrogen oxides (NO_x), unburned hydrocarbon derivatives, and probably particulate matter (soot). The *lifetime* of these species in the atmosphere is relatively short, and if they were distributed evenly, their harmful effects would be minimal.

Unfortunately, these man-made effluents are usually concentrated in localized areas and their dispersion is limited by both meteorological and topographical factors. Furthermore, synergistic effects mean that the pollutants interact with each other: in the presence of sunlight, carbon monoxide, nitrogen oxide(s), and unburned hydrocarbon derivatives lead to photochemical smog, while when sulfur dioxide concentrations become appreciable, sulfur oxide-based smog is formed. It is worth remembering that the non-toxic, but non-life supporting and suffocating, carbon dioxide may have an important effect on the environment. The surface of the earth emits infrared radiation with a peak of energy distribution in the region where carbon dioxide is a strong absorber. This results in the situation whereby the atmosphere traps this infrared radiation, and the temperature of the surface of the Earth is increased.

The three major types of pollutants emitted by the combustion process are particulate matter, sulfur dioxide, and nitrogen oxides (NO_x). Particulate matter arises from minerals in the feedstock that are converted in the combustion process to finely divided fly ash which can be carried out of the stack with the hot exhaust gases; the practice of burning finely divided feedstock contributes to fly ash emissions. There is also the concept that the size of the fly ash has a direct bearing on the physical and chemical properties that can influence the method of disposal.

Sulfur dioxide is produced by the oxidation of organic sulfur in the feedstock and is normally cited as the most troublesome of the pollutants. For example, sulfur dioxide produced in the combustion process reacts with water to produce sulfurous acid and with oxygen and water in the atmosphere to yield sulfuric acid:

sulfurous acid

sulfuric acid

Sulfuric acid contributes to the harmful and extrusive acid rain, often many hundreds of miles from the original source. Sulfur dioxide levels in the flue gas from large furnaces and boilers may be as high as 2,000 ppm. At flame temperatures in the presence of excess air, some sulfur trioxide is also formed:

Only a small amount of sulfur trioxide can have an adverse effect as it leads to the condensation of sulfuric acid and causes severe corrosion. Although diminution of the excess air reduces sulfur trioxide formation considerably, other considerations, such as soot formation, dictate that the excess air level cannot be lowered sufficiently to eliminate sulfur trioxide entirely. For the most part, the nitrogen that is inherent in the organic structure of the feedstock is converted to nitrogen oxides during combustion which also produce acidic products, thereby contributing to the acid rain phenomenon:

nitrous acid

nitric acid

Fluidized-bed combustion generates little, if any, thermal de-NO_x despite the long residence times since the bed temperatures are usually too low; any residual nitrogen oxide is often derived from the fuel nitrogen rather than from the aerial nitrogen.

Although not generally considered to be a major pollutant, hydrogen chloride from inorganic contaminants is gaining increasing recognition as a pollutant arising from the combustion process. Hydrogen chloride quickly picks up water from the atmosphere to form droplets of hydrochloric acid and, like sulfur dioxide, is a contributor to acid rain. However, hydrogen chloride may exert severe local effects because it does not have to undergo any chemical change to become an acid.

Under atmospheric conditions involving a buildup of stack emissions in the area of a large power plant, the concentration of hydrochloric acid in rain droplets could be quite high. Little, if anything, can be done as part of the feedstock pretreatment operation(s) to eliminate nitrogen because this element is a part of the organic structure of the feedstock. The situation is less clear in the case of hydrogen chloride sources in the feedstock. Both organically-bound chlorine and inorganic chloride salts contribute appreciably to hydrogen chloride formation during combustion, but these processes do not remove organically-bound chlorine, which is a more likely precursor to hydrogen chloride in a combustion process.

Appropriate processing can reduce both the mineral matter (the precursor to the ash) and the sulfur content. As with inorganic chlorides, washing processes are the most successful methods for removing inorganic sulfur but they do not affect the organic sulfur content. Most stack gas scrubbing processes are designed for sulfur dioxide removal; nitrogen oxides are controlled as far as possible by modification of combustion design and flame temperature regulation. However, processes for the removal of sulfur dioxide usually do remove some nitrogen oxides; particulate matter can be removed efficiently by commercially well-established electrostatic precipitators.

There are several processes for the removal of sulfur dioxide from stack gas, but scrubbing process utilizing limestone (CaCO_3) or lime [$\text{Ca}(\text{OH})_2$] slurries has received more attention than other stack gas scrubbing processes. Attempts have been made to use dry limestone or dolomite ($\text{CaCO}_3 \cdot \text{MgCO}_3$) within the combustor as an “in situ” method for sulfur dioxide removal, thus eliminating the wet sludge from wet processes. This involves injection of dry carbonate mineral with the feedstock followed by recovery of the calcined product along with sulfite and sulfate salts:

The various solid products are removed by standard means, including cyclone separators and electrostatic precipitators.

The non-volatile oxidation products of the inorganic constituents of the feedstock (such as sodium and potassium) are left as oxides in the combustion ash and contribute to the formation of corrosive deposits. When the feedstock is pulverized prior to the combustion process, a large proportion of the ash is carried out of the combustion chamber with the exhaust gas stream and has to be removed as completely as possible, usually by use of electrostatic precipitators. The removal of fly ash from combustion effluent streams is as important to the environment as the removal of sulfur oxides and nitrogen oxides. If not removed, the inorganic constituents and the organic constituents of the ash can cause serious environmental consequences, in addition to the solid particles acting as condensation nuclei and (catalytic) surfaces for the conversion of sulfur dioxide to the trioxide:

Because of its organic origin of the feedstock and its intimate co-mixture with mineral, the biomass feedstock may contain a large number of elements in minor or trace quantities. In regard to the behavior of trace elements in biomass, the elements have been divided into two groups, those appearing mainly in the bottom ash (elements or oxides having lower volatility) and those appearing mainly in the fly ash (elements or oxides having higher volatility).

For power plants using dry particulate collection devices, such as electrostatic precipitators, it was believed that the most volatile elements (such as mercury and selenium) could actually escape in the elemental state with the flue gas; wet scrubbers, however, were believed capable of removing most of the elements from the gas streams and transferring them to the liquid effluent. Essentially no particulate matters from the combustion process should be ejected into the atmosphere; all particulate streams should be collected and either returned to the combustors, where they melt and are removed as slag, or are removed as fly ash.

Any eventual dispersion of the elements present depends on the possibility of leaching. The concern, therefore, is to identify elements that may be occurring in the gaseous state. Among the trace elements that may be present in combustion feedstocks (such as biomass and waste) with recognized toxic properties, high-volatility elements (beryllium, mercury, and lead) do not form gaseous-hydrides, will condense on cooling, and likely will be almost completely removed by the aqueous condensates formed on gas cooling and/or purification. Arsenic, antimony, and selenium have lower volatility but can form gaseous hydrides, (covalent) hydrides: arsine, Stibine, and hydrogen selenide. These however, have stability characteristics that preclude their formation at the temperature and pressure prevailing in the oil/gas plant gasifiers.

Combustion – Fluidized Bed

Fluidized bed combustion (fluid bed combustion, FBC) is a combustion technology in which a fluidized bed suspends the solid fuel on upward-blowing jets of air during the combustion process. The result is a turbulent mixing of gas and solids.

The tumbling action, much like a bubbling fluid, provides more effective chemical reactions and heat transfer. Fluid bed combustors are more flexible than conventional plants in that they can be fired on biomass as well as coal. Fluid bed combustion systems fit into two major groups which are (i) atmospheric systems – the fluidized bed combustor and (ii) pressurized systems – the pressurized fluidized bed combustor.

Atmospheric fluidized bed systems use limestone or dolomite to capture sulfur released during the combustion. Jets of air suspend the mixture of sorbent and burning coal during combustion, converting the mixture into a suspension of red-hot particles that flow like a fluid.

Pressurized fluid bed systems also use a sorbent and jets of air to suspend the mixture of sorbent and burning coal during combustion. However, these systems operate at elevated pressures and produce a high-pressure gas stream at temperatures that can drive a gas turbine. Steam generated from the heat in the fluidized bed is sent to a steam turbine, creating a highly efficient combined cycle system.

Fluid bed combustion reduces the amount of sulfur emitted in the form of sulfur dioxide emissions. Limestone can be used to precipitate out sulfate during combustion, which also allows more efficient heat transfer from the boiler to the apparatus used to capture the heat energy (usually water tubes). The heated precipitate coming in direct contact with the tubes (heating by conduction) increases the efficiency. Since this allows the process to use lower temperatures (approximately 800°C/1,500°F), less nitrogen oxide is also emitted. However, burning at low temperatures also causes increased polycyclic aromatic hydrocarbon emissions.

This method of incineration uses is a viable alternative to the mass burn system. The pellets are fed onto a bed consisting of a mixture of sand and dolomite mineral. Air is then pumped through the whole mixture to create a bubbling liquid. The waste in this new liquid form has an improved combustion efficiency that reduces pollution and increases generation per ton of waste. This type of system may be slower than moving bed combustion.

Combustion – Fouling

Fouling is the accumulation of small, sticky molten particles of coal ash on a boiler surface.

Coal combustion is, on the one hand, a balance of high reaction or flame temperatures which favor carbon monoxide at equilibrium and, on the other hand, the use of excess air which drives the conversion to carbon dioxide. Relative to these two opposing reactions, the rates of reaction are generally controlling and manifested by short residence times with rapid heat transfer such that the system temperature is lowered before equilibrium can occur,

hence the consideration that (complete) combustion is a non-equilibrium process. This is contrary to gasification by partial combustion, which occurs at lower temperatures and longer residence times without heat transfer (the system remains adiabatic), where equilibrium conditions tend to apply.

Though thermodynamic and rate calculations may be used to maximize flame temperatures and conversions, it is the empirical observation and evidence in each situation that will dictate the optimum air-to-fuel ratio and will depend on fuel analysis including moisture, air humidity and temperature, and other general operating variables. Although 15 to 25% v/v excess air is a median range, it depends not only on the fuel but also on the type of combustion system and the control of that system.

The ash is composed mostly of metal oxides, and the composition affects the softening point. Iron oxides are a particular source of problems, and the reducing atmosphere ($\text{CO} + \text{H}_2$; produced by the water gas reaction) in the fuel bed serves to reduce ferric oxide (Fe_2O_3) to ferrous oxide (FeO) with the production of *clinker* which will contribute to reactor fouling.

In addition, the fouling of combustion systems has also been related to the alkali metals content of biomass and waste. For example, a feedstock with a total alkali metal content on the order of <0.5% w/w (as equivalent sodium oxide, Na_2O) produces deposits that can be removed by the action of soot blowers (perforated lances through which jets of high-pressure air or steam can be sent between boiler tubes), but for a feedstock having more than 0.6% w/w alkali metal (as equivalent sodium oxide), the deposits can increase markedly and can be a major problem.

To combat fouling, modern combustion equipment is designed to ensure that particles are cooled to well below their fusion temperatures before they can reach the banks of closely spaced tubes in the upper regions of the boiler. In pulverized fuel systems, provision is usually made for tilting the burners and thereby periodically altering the heat regime. In addition, tube deposits are routinely dislodged by frequent *soot blowing*.

Combustion – Heat Balance

The heat balance of the combustion process provides a relative weighting of the heat input into the system versus the heat output of the process:

$$dH_I \rightarrow dH_c + S_H + dH_E$$

In this equation, dH_c is the heat input, S_H is a composite of the sensible and latent heats of air, fuel, and other materials, and dH_E is the heat from exothermic reactions (other than combustion) which may contribute to the overall combustion process:

$$dH_o \rightarrow dH_{cu} + S_{HC} + dH_{-E} + dS_{AG} + dH_L$$

Here, dH_o is the heat output, dH_{cu} is the heat of combustion of unburned fuel, S_{HC} is the sensible and latent heats in the carbonization products, dH_{-E} is the heat absorbed by endothermic reactions, dS_{AG} is the sensible and latent heats in the combustion products (ash and stack gases), and dH_L is the heat losses to the surroundings by convection, radiation, and combustion.

The presence of water vapor in the combustion system appears in the latent heat effects, and one consequence of high moisture content in coal combustion is that a part of the heat is lost due to evaporation of the moisture in the coal and is not recouped from the combustion products. A small amount (<5% w/w) of water in the feedstock may not exert any marked effect on the overall heat requirements, since the sensible heat of the gases vaporizes the water.

Combustion – Ignition

The ignition of the carbonaceous feedstock has been described as occurring in just a few hundredths of a second with the onset of burning in less than half a second. The ignition distance has been observed to be on the order of 0.04 in (1 mm) with the carbon monoxide formed by reaction at the surface burning to carbon dioxide at distances close to the surface (0.5 to 4 mm). Water is evaporated in the initial stages, and the ignition is propagated through a dry bed.

Combustion – Influence of Feedstock Quality

Feedstock quality is recognized as having an impact, often significant, on combustion, especially on many areas of the combustion system. The parameters of carbon content, hydrogen content, rank, mineral matter content (ash content), sulfur content, and moisture content are regarded as determining factors in combustibility as it relates to both heating value and ease of reaction.

Finally, since feedstock quality can be affected by oxidation or weathering, the question is raised related to the effects of oxidation and weathering on combustion and whether oxidized feedstock could maintain a self-sustaining flame in an industrial boiler. The inhibition of volatile matter release due to changes in the char morphology as a result of the oxidation/weathering suggests that this may not be the case.

One option for managing feedstock quality is to blend one particular feedstock with others until a satisfactory quality is achieved. This is similar to current crude oil refinery practice where one refinery actually accepts a blend of various crude oils and operates on the basis of average feedstock composition.

Combustion – Mechanism

The exact nature of the combustion process is difficult to resolve but can be generally formulated as two processes which are (i) the degradation of hydrogen, and (ii) the degradation of carbon. It is also necessary to understand the surface chemistry involved in the burning process, and progress is being made in this direction. However, biomass and waste feedstocks being heterogeneous solids add an increasingly difficult dimension to the combustion chemistry and physics; combustion actually occurs on the surface with the oxidant being adsorbed there prior to reaction. However, the initial reaction at (on) the surface is not necessarily the rate-determining step; the process involves a sequence of reactions, any one of which may control the rate.

The initial step is the transfer of reactant (i.e., oxygen) through the layer of gas adjacent to the surface of the particle. The reactant is then adsorbed and reacts with the solid after which the gaseous products diffuse away from the surface. If the solid is porous, much of the available surface can only be reached by passage of the oxidant along the relatively narrow pores and this may be a rate-controlling step. Rate control may also be exercised by: (a) adsorption and chemical reaction, which are considered as chemical reaction control; and (b) pore diffusion, by which the products diffuse away from the surface. This latter phenomenon is seldom a rate-controlling step.

In general, rate control will occur if the surface reaction is slow compared with the diffusion processes; while diffusion shows a less-marked temperature dependence, reaction control predominates at low temperatures, but diffusion control is usually more important at higher temperatures. In fact, on a chemical basis, hydrogen degradation outweighs the slower-starting carbon degradation in the early, or initial, stage of combustion. But, at the same time, the carbon monoxide/carbon dioxide ratio is decreased.

After the initial stages of combustion, during which volatile material is evolved (which is also combustible), a nonvolatile carbonaceous residue (coke, char), which can comprise up to 90% of the original mass of the feedstock, remains. During the combustion of the coke, three different zones (regimes) of combustion can be distinguished.

In the first zone (I), the rate of diffusion to and away from the surface is fast compared with the rate of the surface reaction; such phenomena are observed at low temperatures. At much higher temperatures, the rate at which oxygen molecules are transported from the bulk gas to the external surface is slow enough to be rate controlling (Zone III); the observed rate can be equated to the molar flux of oxygen to unit area of external surface. Finally (Zone II; intermediate between I and III), the oxygen transport to the external surface is rapid but diffusion into the pores before reaction is relatively slow.

In practice, there are considerable differences between the reactivity of different cokes, some of which can be assigned to variations in pore structure and others to the presence of impurities (e.g., alkali metal salts) which have a pronounced catalytic effect on the surface reaction. Consequently, the temperature ranges corresponding to the three zones differ and are not constant for different cokes/chars.

There are alternate ways to consider the mechanism of combustion, and there is a variety of models proposed for this purpose. For example, in a simple model for the combustion process, the initial step is assumed to be (i) devolatilization, (ii) ignition, and (iii) rapid burning of the volatiles relative to the char. But the actual mechanism is considered to be somewhat more complex. The process is thought to consist of (i) diffusion of reactive gases to the carbon surface, (ii) adsorption, (iii) formation of transitory complexes, and (iv) desorption of the products, but the overall reaction mechanism for a devolatilized char particle is believed to be (i) transport of oxygen to the surface of the particle, (ii) reaction with the surface, and (iii) transport of the products away from the surface.

As the pressure of the system is increased, the mechanism tends toward diffusion control. This is due to the mass transfer or diffusion rate coefficient being inversely proportional to pressure. The overall rate, however, will increase due to the increased oxygen partial pressure at the higher pressures.

The complexity of many carbonaceous feedstocks has resulted in treatments of the combustion process being confined to the carbon in the system and, to a lesser extent, the hydrogen, but it must be recognized that the system is extremely complex. Even with this simplification, there are several principal reactions that are considered to be an integral part of the overall combustion process.

In summary, it is more appropriate to consider the combustion of carbonaceous materials (which contain carbon, hydrogen, nitrogen, oxygen, sulfur, and mineral matter) as involving a variety of reactions between (i) the reactants, (ii) the intermediate, or transient, species, and (iii) the products. The reactions can occur both simultaneously and consecutively (in both forward and reverse directions) and may even approach steady-state (equilibrium) conditions. Moreover, there is a change in the physical and chemical structure of the fuel particle during the process.

Combustion – Soot Formation

The formation and possible emission of soot is often observed during combustion of fuels, such as biomass and waste. Soot consists of carbonaceous particles formed during combustion, and can be identified in flames and fires as yellow luminescence. In modern practical combustion devices, the formation of soot is mostly an unwanted process, since strict legislation on emission levels applies, and soot is known to play a significant effect on health.

Soot formation involves several steps which are (i) the construction of a sub-nanometer polycyclic aromatic hydrocarbon derivatives, sometimes referred to as seeds, (ii) the growth of that small seed to the size of a few nanometers as it passes through a mixture of unburned or partially burned molecules, and (iii) the self-agglomeration of these larger particles to form particles tens to hundreds of nanometers in size. The first step of seed construction that is thought to proceed through at least two mechanisms and which mechanism dominates under different conditions that are not accurately known.

Combustion – Surface Effects

The ignition of a carbonaceous feedstock has been described as occurring in just a few hundredths of a second with the onset of burning in less than half a second. The ignition distance has been observed to be on the order of 0.04 in (1 mm) with the carbon monoxide formed by reaction at the surface burning to carbon dioxide at distances close to the surface (0.5–4 mm). Water is evaporated in the initial stages, and the ignition is propagated through a dry bed.

The conditions under which a feedstock ignites and the behavior during ignition will relate to (i) the structure of the volatilized constituents and (ii) the temperature in the coke-burning state. In addition, some consideration must be given to the manner in which the volatile matter is released. For example, the particle may burn by first releasing all the volatile matter which may burn simultaneously with the carbon. It does, however, seem unlikely that oxygen would reach the surface in the presence of volatiles and, thus, any oxygen attempting to diffuse through the volatiles layer would react instead.

Generally, it is possible to subdivide the overall reaction sequence into (i) those reactions which could conceivably occur at the surface of the char and (ii) those reactions which may occur between the gaseous products themselves.

During combustion, there are several possibilities for the mode in which the carbon reacts in the particle structure. The carbon may react only from the surface, and reaction may proceed uniformly throughout the particle, or, alternately, the particle may be regarded as a hollow sphere with burning occurring on both the outer and inner surfaces. In fact, there is evidence that particles do form hollow spheres during combustion and such spheres (cenospheres) are believed to be formed during volatilization. The porous structure of the carbonized char also exerts an effect on the burning operation as does particle temperature up to several hundred degrees above the gas temperature.

Combustion Technologies

Stokers currently used in wood-fired applications fall into two major categories, the air-cooled traveling grate and water-cooled stationary grate. With both of these types of stokers, the wood fuel is distributed across the width of the grate with metering bins on the front wall of the boiler. The fuel is then uniformly distributed over the depth of the grate by air-swept spouts.

Sawdust and other fines in the fuel are burned in suspension, while larger particles drop to the grate and are dried and burned directly on the grate surface. Heated low-pressure combustion air is evenly distributed through the grate surface to promote fuel drying and provide the primary source of combustion air. To further aid the combustion

process, high-pressure over fire air ports are used above the grate to provide turbulence and thorough mixing of the unburned combustion gases with air.

With the traveling stoker, the grate travels from the rear of the boiler to the front with fuel being fed across the depth of the furnace to the rear wall. Ash travels to the front edge of the grate and falls into a pit. This design requires additional maintenance due to the high temperatures that the grate bars are exposed to and the abrasive nature of the wood ash due to the high silica content.

The Detroit hydro-grate stoker typifies the stationary water-cooled grate. With this design, the grate bars are attached to a water-cooled tubular grid and the grate is sloped at a slight angle (approximately 6-8 degrees) and is periodically vibrated to assist the movement of the burning fuel and ash down the grate toward the ash pit. The advantage of a water-cooled grate is the reduced maintenance from the minimum of moving parts. Care must be taken in operation not to permit an ash pit fire. This will result in overheating and failure of the water supply tubes feeding the grate's support grid.

Both of these two types of stokers are commercially proven technologies that are highly flexible in the choices of fuels that can be burned, alone or in combination. Turndown and response to rapid load swings with little or no change in steam temperature or pressure are also good.

The application of wood-fired circulating fluidized bed boilers (CFB) has generally been limited to waste wood products that are significantly drier than biomass from the forest. Typically, circulating fluidized bed boilers use fuels such as demolition wood waste and mill residues but they can be easily designed to fire higher moisture wood fuels, alone or in combination with other solid fuels.

In a circulating fluidized bed boiler unit, fuel is fed into the lower part of the furnace. The fuel mixes with the fluidized bed where the solids are maintained at 815 to 870°C (1,500 to 1,600°F). The fuel introduced to the bed is quickly heated until it reaches ignition temperature. As the fuel burns, the size is reduced to a point where the particles are entrained by the upward flow of combustion gases. Larger particles are removed from the gas stream before it reaches the convection surfaces of the unit by use of a cyclone or particle collector beams, and they are returned to the bed for further burnout and size reduction. The advantages of a circulating fluid bed unit includes the ability to burn lower grade fuels at reduced temperatures and excess air without loss of combustion efficiency. In addition to the reduced NO_x and SO_x emissions that are inherent with a circulating fluid bed, these units can burn high-fouling fuels without the normally associated operating problems due to the reduced combustion temperatures. Circulating fluid bed units will suffer from bed sintering from firing fuels that have high alkali metal content. This will result in higher fouling of the bed tube surfaces and excessive above bed burning that will increase furnace exit gas temperatures and superheater fouling. Units equipped with refractory lined cyclones will also have high refractory maintenance requirements due to the abrasive nature of the ash.

The application of wood-fired bubbling fluidized bed boiler (BFB) units is much more widespread than the circulating fluid bed units. Due to their ability to burn high moisture, low-Btu fuels, they have been uniquely suited to the needs of the pulp and paper industry to burn biomass, wood waste, and bark commonly produced in large quantities at a pulp mill.

The fuel feeding and combustion process for a bubbling fluid bed unit is similar to that of a circulating fluid bed unit except that the bed is only partially fluidized, and the burning fuel is not entrained in the combustion gas flow and remains in the bed. The advantage of a bubbling fluidized bed unit is its ability to burn difficult low-grade wet fuels. The thermal inertia of the bed and the mechanical action of the sand and ash to break down the fuel particles make a bubbling fluidized bed unit insensitive to fuel variations. Unlike a circulating fluid bed unit, a bubbling fluid bed unit utilizes a non-circulating bed in the furnace bottom that is made up of sand. The wood ash and a small amount of sand are removed through a drain opening in the floor of the furnace to control the bed level. The sand acts as a thermal reservoir, and it mechanically breaks down the size of the fuel to facilitate combustion. Bubbling fluid bed units do suffer from the same bed sintering problems as the circulating fluid bed units, but due to the partially fluidized bed, the sintering problems can be much worse and can result in high sand consumption rates due to the high bed drain rates.

The inclined fluidized bed (IFB) technology combines aspects of the inclined grate and fluidized bed technologies. Unlike most other technologies that mechanically agitate the fuel during combustion, the inclined fluidized bed uses an entirely different concept for performing this function. With the inclined fluidized bed technology, the fuel

is fed onto an inclined grate assembly via a feed ram where controlled combustion takes place. Combustion air is provided to each portion of the grate from a combustion air fan through slots in the grate assembly.

The inclined fluidized bed grate utilizes hollow tubes to form the steps on the grate. Each of the tubes is equipped with a number of small nozzles that provide a passage from the tubes to the fuel bed on the grate. The tubes are connected to a common fan that recycles a portion of the exhaust gas. This gas is introduced into the fuel bed as short pressure pulses, controlled by valves on an intermittent basis, providing a burst of energy into the fuel bed. These pulses result in highly efficient agitation of the fuel. The fuel is pneumatically mixed in lieu of a mechanical means, thereby providing efficient oxidation of the fuel. This technology uses fewer moving parts, which reduces both the equipment capital costs and the maintenance costs. Inclined fluidized bed FB grates are new and have not yet been utilized in an industrial wood-fired application, although pilot-scale testing has been successful.

Combustion – Types of Combustors

The combustor (incinerator) is, simply, a furnace for burning refuse, and modern combustors include pollution mitigation equipment such as flue-gas cleaning. There are various types of combustor plant design: (i) simple combustor, (ii) fixed or moving grate combustor, (iii) rotary-kiln combustor, and (iv) the fluidized bed combustor.

The simple combustor is an older and simpler kind of combustor that is, essentially, a brick-lined cell with a metal grate over a lower ash pit, with one opening in the top or side for loading and another opening in the side for removing incombustible solids (clinker). Many small combustors formerly found in apartment houses have now been replaced by waste compactors.

The fixed or moving grate combustor is a fixed hearth combustor with a moving grate. The moving grate enables the movement of waste through the combustion chamber to be optimized to allow a more efficient and complete combustion. These combustors are typically used for combustion of municipal waste, and are thus referred to as MSWCs (municipal solid waste combustors).

In the fixed or moving grate combustor, the waste is introduced by a waste crane through the “throat” at one end of the grate, from where it moves down over the descending grate to the ash pit in the other end. Here, the ash is removed through a water lock. Part of the combustion air (primary combustion air) is supplied through the grate from below. This air flow also has the purpose of cooling the grate itself. Cooling is important for the mechanical strength of the grate, and many moving grates are also water-cooled internally. Secondary combustion air is supplied into the boiler at high speed through nozzles over the grate. It facilitates complete combustion of the flue gases by introducing turbulence for better mixing and by ensuring a surplus of oxygen.

The combustor must be designed to ensure that the flue gases reach a temperature of at least 850°C (1,560°F) in order to ensure proper breakdown of organic toxins. This includes backup auxiliary burners (often fueled by oil), which are fired into the boiler in case the heating value of the waste becomes too low to reach this temperature alone. The flue gas is then cooled by heat transfer and heat the steam to typically 400°C (750°F) at a pressure of 550 to 600 psi for the electricity generation in the turbine. At this point, the flue gas has a temperature of around 200°C (390°F), and is passed to the flue gas cleaning system.

In the fixed or traveling grate combustor, an automatic feeder distributes the fuel onto a grate, where the fuel burns. Combustion air enters from below the grate. In the stationary grate design, ashes fall into a pit for collection. In contrast, a traveling grate system has a moving grate that drops the ash into a hopper. In another configuration, a *pile burner* consists of separate cells and each cell consists of an upper and a lower combustion chamber for use in a step-wise burner configuration. In this type of equipment, the biomass feedstock combusted burns on a grate in the lower chamber thereby releasing volatile gases which are then combusted in the upper (secondary) combustion chamber. However, pile burners must be shut down periodically to remove the mineral ash.

The rotary kiln combustor has a primary chamber and secondary chamber. The primary chamber consists of an inclined refractory lined cylindrical tube. Movement of the cylinder on its axis facilitates movement of waste. In the primary chamber, there is conversion of solid fraction to gases, through volatilization, destructive distillation, and partial combustion reactions. The secondary chamber is necessary to complete gas phase combustion reactions.

The clinker spills out at the end of the cylinder. A tall flue gas stack, fan, or steam jet supplies the needed draft. Ash drops through the grate, but many particles are carried along with the hot gases. The particles and any combustible gases may be combusted in an *afterburner*. To control air pollution, the combustion product gases are further treated with acid gas scrubbers to remove sulfuric acid and emissions of nitric acid, and then routed through bag houses to remove particulate matter before the gas is released into the atmosphere.

The fluidized bed combustor uses a strong airflow through a sand bed until a point is reached where the sand particles separate to let the air through and mixing and churning occurs, thus a fluidized bed is created and fuel and waste can now be introduced. The sand with the pre-treated waste and/or fuel is kept suspended on pumped air currents and takes on a fluid-like character. The bed is thereby thoroughly mixed and agitated keeping small inert particles and air in a fluid-like state. This allows all of the mass of waste, fuel, and sand to be fully circulated through the furnace.

Fluidized-bed combustors burn biomass fuel in a hot bed of granular material, such as sand. Injection of air into the bed creates turbulence resembling a boiling liquid. The turbulence distributes and suspends the fuel. This design increases heat transfer and allows for operating temperatures up to 970°C (1,700°F), reducing nitrogen oxide (NO_x) emissions. Fluidized-bed combustors can handle high-ash fuels and agricultural biomass residue.

The heat produced by a combustor can be used to generate steam which may then be used to drive a turbine in order to produce electricity. However, the amount of energy produced is very much dependent upon the type and composition of the waste used as the feedstock. Much of the current thinking involves co-combustion of a specified amount of the waste (calculated on the basis of the carbon content of the waste) with, for example, coal to produce a consistent amount of energy. However, the combustion process has a number of outputs such as (i) the mineral ash and (ii) the emission to the atmosphere of flue gas. Before the flue gas cleaning, the flue gases may contain significant amounts of particulate matter, heavy metals, dioxin derivatives, furan derivatives, sulfur dioxide, hydrochloric acid, and polynuclear aromatic hydrocarbon derivatives (carcinogens).

The most publicized concerns related to the combustion of municipal solid wastes involve the fear that it produces significant amounts of emissions of dioxin and furan derivatives which are considered by many to be serious health hazards. Older-generation combustors that were not equipped with modern gas cleaning technologies were indeed significant sources of dioxin emissions. However, modern combustors (due to advances in emission control designs and stringent regulations) must limit and even mitigate such emissions.

The quantity of pollutants in the flue gas from combustion plants is reduced by several processes. For example, taking an example from the gas processing industry, particulate matter is collected by particle filtration, most often electrostatic precipitators and/or baghouse filters. Hydrogen chloride and sulfur dioxide are removed in scrubbers or as in a dry desulfurization process by injection of a limestone (CaCO₃) as a slurry into the flue gas stream before the particle filtration step. Wastewater from scrubbers must subsequently pass through a wastewater treatment plant. Nitrogen oxide (NO_x) emissions are either reduced by catalytic reduction with ammonia in a catalytic converter (a selective catalytic reduction process) or by a high temperature reaction with ammonia in the furnace (a selective non-catalytic reduction process). Heavy metals are often adsorbed on injected active carbon powder (such as activated charcoal), which is collected by the particle filtration. As is the case when coal is combusted, combustion of biomass or organic waste also produces fly ash and bottom ash.

By way of explanation, heavy metals are generally defined as metals with relatively high density, atomic weight, or atomic number. Fly ash is a combustion product that is composed of the particulates (fine particles of burned fuel) that are driven out of coal-fired boilers together with the flue gases. Fly ash is, thus, that portion of the ash that escapes up the chimney or stack. On the other hand, bottom ash is part of the non-combustible residue of combustion in a power plant, boiler, furnace, or combustor. In an industrial context, it typically comprises traces of combustibles embedded in forming clinkers and sticking to hot side walls of a furnace during its operation. The clinker materials fall by themselves into the bottom hopper of a coal-burning furnace and are cooled. The above portion of the ash is also referred to as bottom ash.

The total amount of ash produced by municipal solid waste combustion ranges from 15 to 20% w/w of the waste, and the fly ash amounts to 0 to 10% w/w of the total ash. The fly ash, by far, constitutes more of a potential health hazard than does the bottom ash because the fly ash often contains high concentrations of heavy metals such as lead, cadmium, copper, and zinc as well as small amounts of dioxin derivatives and furan derivatives. The bottom ash seldom contains significant levels of heavy metals.

While fly ash is always regarded as hazardous waste, bottom ash is generally considered safe for regular landfill after a certain level of testing defined by the local legislation. Ash, which is considered hazardous, may generally only be disposed of in landfills which are carefully designed to prevent pollutants in the ash from leaching into underground aquifers – or after chemical treatment to reduce the leaching characteristics of the ash.

In spite of the promise shown by the use of combustors for waste disposal and, in some cases, energy production (in the form of fuel gases), the use of combustors for waste combustion is often controversial. On the one hand, the concerns over the health effects of the emissions of furan derivatives and dioxin derivatives have been significantly lessened by advances in emission control designs and very stringent new governmental regulations that have resulted in large reductions in the amount of dioxin derivatives and furan derivatives emissions emitted into the environment.

However, there may be concerns related to the health effects of furan and dioxin emissions into the atmosphere from old combustors. Also, combustors emit varying levels of heavy metals such as (alphabetically) arsenic, cadmium, chromium, lead manganese, mercury, nickel, and vanadium, which can be toxic at very minute levels. Other advanced alternative technologies are available such as biological treatment combined with anaerobic digestion and gasification.

Combustion Zone

The combustion zone is where the area feedstock occurs. However, the process that occurs in the combustion zone is not always as straightforward as simple equations indicate.

Combustion, with rare exceptions, is a complex chemical process involving many steps that depend on the properties of the combustible substance. It is initiated by external factors such as heat, light, and sparks. The reaction sets in as the mixture of combustibles attains the ignition temperature. The combustion spreads from the ignition source to the adjacent layer of gas mixture. In fact, each point of the burning layer serves as an ignition source for the next adjacent layer. Combustion terminates when an equilibrium is achieved between the total heat energies of the reactants and the total heat energies of the products. Most reactions terminate when what is called thermal equilibrium has been attained when the energy of the reactants equals the energy of the products.

See also: Combustion.

Combustion Plants

Modern combustion plants generate electricity and heat that can be sold to the regional electric grid and can sell steam to district heating systems or industrial customers. The bottom ash residue remaining after combustion has been shown to be a non-hazardous solid waste that can be safely landfilled or possibly reused. In densely populated areas, finding space for additional landfills is becoming increasingly difficult.

Combustion of municipal solid waste avoids the release of carbon dioxide and methane. Every ton of municipal solid waste incinerated, prevents approximately one ton of carbon dioxide equivalents from being released to

the atmosphere. Combustion of medical waste and sewage sludge produces an end product ash that is sterile and non-hazardous. On the other hand, the end product ash must still be safely sent for disposal. Many countries deny the use of combustion as an option for the treatment of their municipal solid wastes because of the potential of environmental pollution. In addition, combustors produce soot particles ($PM_{2.5}$, nanoparticles, i.e., particles with a size less than 2.5 microns, $<1 \times 10^{-6}$ meter) in the furnace. Even with modern particle filtering of the flue gases – such as baghouse filters – some of these small particles are emitted to the atmosphere.

In summary, combustion is not a complete method of disposal; its main advantage is that it produces a residue that is substantially reduced in volume and may be relatively inert. In addition, the efficiency of a combustor is, on occasion, due to excessive throughput or choice of operating parameters that are less than desired. For example, the operating temperature inside the plant should be at the specified temperature (usually on the order of 850°C, 1,560°F) to reduce the possible effects of the most dangerous air pollutants and the production of dioxins. A lower than specified combustion temperature implies incomplete combustion, leaving part of the waste in the ashes and other combustion residues. Furthermore, the exhaust gases may be unnecessarily polluting because of the low combustion temperature and the by-products of such combustion may be sent to an unprotected landfill for disposal.

Combustion plants are usually classified as mass burn systems or refuse-derived fuel (RDF) systems. In the mass burn system, all waste is incinerated; they are large facilities, over 200 tons (4,000 lbs) per day. Most mass burn systems burn waste in a single combustion chamber with excess air. The waste is burned on a sloping moving grate which helps agitate the municipal solid waste and mixes the waste with combustion air; many different proprietary grate systems exist. Grate design is critical because it must agitate the waste sufficiently to provide complete combustion and minimize ash carry-over in the flue gas which contributes to emissions.

In the boiler/furnace portion of the combustor, the waste characteristics of interest are the calorific value, moisture content, proportion of non-combustibles, and other components such as heavy metals, chlorine, and sulfur whose presence during combustion will result in the need for flue gas cleanup. The capacity of the furnace/boiler of the combustor is approximately proportional to the calorific value of the waste. Mass burn produces by-products which have damaging consequences on the environment. Pollution control systems can be used to mitigate such risks. The technologies used to recover energy from municipal solid waste include (i) waterwall combustion and (ii) modular combustion.

Waterwall combustion involves the combustion of unprocessed municipal solid waste (mass burning) or processed municipal solid waste in a furnace with integral boiler tubes. Waterwall units have been built as small as 75 to 100 tons per day capacity. However, the cost per ton of rated capacity of such units is relatively high. A more common unit size is 250 to 300 tons per day, while waterwall mass-fired units have been built as large as 750 to 1,200 tons per day capacity.

The advantages of waterwall combustion are (i) pre-processing of waste is not required, except for large bulky items; (ii) the ash produced could be used for block manufacture; and (iii) auxiliary fuel is not required during normal steady-state operation. On the other hand, the challenges of water wall combustion are (i) capital and operating costs are high, (ii) complexity of operation, control, and maintenance; and (iii) reserve furnace capacity is not available during downtime. Modular combustion is used in smaller plants and is an assembly of prefabricated major components assembled in the field to form a total operation. Modular combustors have been built in individual unit sizes up to 100 tons per day, combined into plants of just over 400 tons per day.

Modular systems are similar to mass burn systems in that these systems not only combust unprocessed municipal solid waste but also feature two combustion chambers, and the municipal solid waste is charged into the system by a hydraulic ram and combustion takes place on a series of stationary hearths. The municipal solid waste is pushed from one hearth to the next by hydraulic rams. Two types of modular systems have been built and operated: starved air (slightly oxygen deficient) and excess air (greater than stoichiometric).

The advantages of modular combustion are low cost and shorter field construction time given their modular construction. The disadvantages of modular combustion are waste burnout is not always complete (increased ash quantities and reduced energy recovery); combustion control is less effective (possibility of discharge of trace organics); lower quality of equipment; and less redundancy than larger mass-fired water wall and refuse-derived fuel waste to energy plants.

Feedstock preparation plays an important role in any thermal waste conversion approach. Refuse-derived fuel (RDF) is produced when municipal solid waste is processed by mechanical means [picking, separation of inert

materials (glass, minerals, ferrous and non-ferrous metals), flailing, screening, shredding, and conditioning] to produce a more homogenous material prior to combustion. RDF systems utilize pre-treated municipal solid waste. Several types of RDF are generated – coarse, fluff, powder, densified – which differ in complexity, power requirements, particle size and whether the material is compacted into pellets or briquettes. RDF can be used as the primary fuel source in a dedicated boiler or co-fired with a conventional fossil fuel as natural gas or landfill gas. The heating value of nearly all solid waste fuels is a function of carbon content. Ash content is generally low, but the amount of moisture is highly variable and depends upon moisture generation plus the effects of processing, handling, and storage.

Scrap tires can be processed into a waste-derived fuel (WDF) and mixed with other fuels without major alteration to the existing combustion facility. Tire-derived fuels (TDFs) are commonly used as supplemental fuel in cement kilns which are technologically and environmentally superior for selective waste disposal due to favorable internal kiln conditions as flame temperature (1,850°C, 3,360°F), residence time, alkaline environment, high gas turbulence, and mixing which ensure complete combustion, and the added benefit of having no bottom ash disposal problem since the residual materials (e.g., steel from steel-belted tires) are incorporated into the clinker. The rationale behind the use of tire-derived fuel is as follows: (i) excellent combustion characteristics and high heating value, HHV, (ii) lower cost and good availability, (iii) relatively low sulfur content, especially on a Btu basis, and (iv) a reduction in the environmental burden and health effects of tire stockpiles.

Typically, the sulfur content of scrap tires and TDFs is on the order of 1.5 to 2.0% w/w. Considering the emission potential of sulfur dioxide per the generated energy value of the fuel, the result is closer to that for low sulfur-containing coals.

Complete Mix Digester

A complete mix digester converts organic waste to biogas in a heated tank above or below ground. A mechanical or gas mixer keeps the solids in suspension. Complete mix digesters are expensive to construct and cost more than plug-flow digesters to operate and maintain.

Complete mix digesters are suitable for larger manure volumes having solids concentration of 3 to 10%. The reactor is a circular steel or poured concrete container. During the digestion process, the manure slurry is continuously mixed to keep the solids in suspension. Biogas accumulates at the top of the digester. The biogas can be used as fuel for an engine-generator to produce electricity or as boiler fuel to produce steam. Using waste heat from the engine or boiler to warm the slurry in the digester reduces retention time to less than 20 days.

See also: Aerobic Digestion, Anaerobic Digestion, Digester.

Concentrated Acid Hydrolysis

This process is based on concentrated acid decrystallization of cellulose followed by dilute acid hydrolysis to sugars at near theoretical yields. Separation of acid from sugars, acid recovery, and acid reconcentration are critical unit operations. Fermentation converts sugars to ethanol.

The heart of the process is the decrystallization followed by dilute acid hydrolysis. The original Peoria process, developed by USDA researchers in World War II, and a modified version proposed by Purdue, carry out dilute acid pretreatment to separate the hemicellulose before decrystallization. The biomass would then be dried to concentrate the acid absorbed in the biomass prior to addition of concentrated sulfuric acid. Purdue proposed recycling sulfuric acid by taking the dilute acid/water stream from the hydrolysis reactor and using it in the hemicellulose pretreatment step.

In the Arkenol process, decrystallization is carried out by adding 70% to 77% sulfuric acid to biomass that has been dried to 10% moisture. Acid is added at a ratio of 1.25:1 (acid: cellulose + hemicellulose), and temperature is controlled at less than 50°C (122°F). Adding water to dilute the acid to 20% to 30% and heating at 100°C (212°F) for an hour results in the release of sugars. The gel from this reactor is pressed to remove an acid/sugar product stream. Residual solids are subjected to a second hydrolysis step. The use of a chromatographic column to achieve a high yield and separation of acid and sugar is a crucial improvement in the process. The fermentation converts both the

xylose and the glucose to ethanol at theoretical yields of 85% and 92%, respectively. A triple effect evaporator is required to reconcentrate the acid.

Condensation

Condensation occurs when the air becomes saturated with moisture (relative humidity = 100%). As the temperature falls, the relative humidity of the air rises – the temperature at which condensation begins is the dew point. Condensation typically occurs on preexisting surfaces such as dust particles and aerosols to form tiny cloud droplets. The droplets are readily kept airborne by air turbulence until they become so common. As the droplets collide and coalesce, the larger droplets fall, colliding with other droplets to eventually form a raindrop (containing approximately one million cloud droplets). With decreasing temperatures (less than -10°C , 14°F), ice crystals replace water droplets.

The phase change that accompanies water as it moves between the vapor, liquid, and solid forms is exhibited in the arrangement of water molecules, which are arranged more randomly than in liquid water. As condensation occurs and liquid water forms from the vapor, the water molecules become more organized and heat is released into the atmosphere.

Even though clouds are absent in a crystal-clear blue sky, water is still present in the form of water vapor and droplets which are too small to be seen. Depending on weather conditions, water molecules will combine with tiny particles of dust, salt, and smoke in the air to form cloud droplets, which combine and grow and develop into clouds, a form of water we can see. Cloud droplets can vary greatly in size, from 10 microns (millionths of a meter) to 1 millimeter (mm), and even as large as 5 mm. This process occurs higher in the sky where the air is cooler and more condensation occurs relative to evaporation. As water droplets combine (also known as coalescence) with each other, and grow in size, clouds not only develop, but precipitation may also occur. Precipitation is essentially water in its liquid or solid form falling from the base of a cloud. This seems to happen too often during picnics or when large groups of people gather at swimming pools.

The clouds formed by condensation are an intricate and critical component of Earth's environment. Clouds regulate the flow of radiant energy into and out of Earth's climate system. They influence the Earth's climate by reflecting incoming solar radiation (heat) back to space and outgoing radiation (terrestrial) from the Earth's surface. Often at night, clouds act as a "blanket," keeping a portion of the day's heat next to the surface. Changing cloud patterns modify the Earth's energy balance, and, in turn, temperatures on the surface of the Earth.

Coniferyl Alcohol

Coniferyl alcohol is a colorless crystalline organic compound that occurs in gymnosperm and angiosperm plants. Sinapyl alcohol and paracoumaryl alcohol – the two other lignin isomers – are found in angiosperm plants and grasses.

Coniferyl alcohol

Coniferyl alcohol is a phytochemical that is synthesized via the phenylpropanoid biochemical pathways. When copolymerized with related aromatic compounds, coniferyl alcohol forms lignin and lignans.

In softwood species, coniferyl alcohol is the dominant monomer (94% coniferyl, 1% sinapyl, 5% coumaryl alcohols). In hardwood species, both coniferyl alcohol and sinapyl alcohols are present in significant amounts, whereas grasses have large quantities of all three phenyl propylene derivatives.

See also: Hardwood, Grasses, Lignin, Sinapyl Alcohol, Softwood, Paracoumaryl Alcohol.

Conservation

The term conservation refers to the more efficient use of the existing natural resources. Clearly, maximizing conservation is an important and worthwhile contribution to help alleviate existing and future energy problems. Although substantial efforts have already been made toward improving conservation, there are still many more opportunities that have yet to be exploited.

There are two ways by which conservation can be implemented, one of which has a good chance of acceptance by the public and the other which is on much shakier ground. Although both approaches conserve energy, they are separated by a relatively clear line in the sand. The attractive approach takes advantage of advances in technology to conserve fuel while maintaining performance in appliances, automobiles, and other equipment used in daily living. Examples of this approach include hybrid automobiles, more efficient appliances, and additional insulation for older homes.

The second and more difficult approach to conservation requires that citizens directly reduce their use of energy in certain aspects of their daily living. Often, this is viewed as a reduction in standard of living. The public is in general much more reluctant to give up something to which they are already accustomed. Examples of this approach to conservation include smaller, more gasoline-efficient automobiles, smaller houses, increased use of public transportation, less use of air conditioning in summer, and lower thermostat settings in the winter.

With the continually increasing demand for new electricity, particularly by some of the developing nations, it is difficult to imagine that conservation can completely solve the world's future electricity generation problems. Nevertheless, it can reduce the magnitude of the problems. This would afford the nations of the world more time to develop and transition to new alternatives.

See also: Conservation Reserve Program

Conservation Reserve Program

The conservation reserve program (CRP) provides farm owners or operators with an annual per-acre rental payment and half the cost of establishing a permanent land covers in exchange for retiring environmentally sensitive cropland from production for 10 to 15 years. In 1996, Congress reauthorized CRP for an additional round of contracts, limiting enrollment to 36.4 million acres at any time.

The 2002 Farm Act increased the enrollment limit to 39 million acres. Producers can offer land for competitive bidding based on an Environmental Benefits Index (EBI) during periodic signups, or can automatically enroll more limited acreages in practices such as riparian buffers, field windbreaks, and grass strips on a continuous basis. CRP is funded through the Commodity Credit Corporation (CCC).

Contaminant

A contaminant, which is not usually classified as a pollutant unless it has some detrimental effect, can cause deviation from the normal composition of an environment. On the other hand, a receptor is an object (animal, vegetable, or mineral) or a locale that is affected by the pollutant.

In environmental chemistry, the term contaminant is, in some cases, used to be equivalent to pollutant, where the main interest is the harm done on a large scale to humans, organisms, or environments. An environmental contaminant may be chemical in nature, though it may also be a biological (such as pathogenic bacteria, virus, and invasive species) or physical (energy) agent.

See also Pollutant.

Contingent Resources

Contingent resources (sometimes referred to as probable resources or possible resources) are those quantities of crude oil that are estimated, on a given date, to be potentially recoverable from known accumulations, but which are not considered as commercially recoverable (Table C-9).

Table C-9 Categorization of resources and reserves.

Resource	Undiscovered			
	Discovered			
		Nonrecoverable		
		Recoverable		
			Cumulative production	
			Reserves	Unproved
			(actual)	Probable
				Possible

Some ambiguity may exist between the definitions of contingent resources and unproved reserves. This is a reflection of variations in current industry practice, but if the degree of commitment is not such that the accumulation is expected to be developed and placed on production within a reasonable time frame, the estimated recoverable volumes for the accumulation can be classified as contingent resources. Contingent resources may include, for example, accumulations for which there is currently no viable market, or where commercial recovery is dependent on the development of new technology, or where evaluation of the accumulation is still at an early stage.

Conventional Fuel Sources

Crude oil is recognized as the prominent conventional fuel source. Thus, in the context of the definition of a renewable fuel or synthetic fuel that is defined in the context of substitutes for crude oil-based fuel (q.v.), the term conventional fuel implies any available fuel derived from crude oil.

Crude oil and the equivalent term crude oil cover a vast assortment of materials that consist of gaseous, liquid, and solid hydrocarbon-type chemical compounds that occur in sedimentary deposits throughout the world. When crude oil occurs in a reservoir that allows the crude material to be recovered by pumping operations as a free-flowing dark-to -light-colored liquid, it is often referred to as conventional crude oil.

The United States Congress has defined tar sands as several rock types that contain an extremely viscous hydrocarbon which is not recoverable in its natural state by conventional oil well production methods including currently used enhanced recovery techniques. By inference, heavy oil, which can be recovered in its natural state by conventional oil well production methods including currently used enhanced recovery techniques, does not fall into the same category as tar sand bitumen and therefore is a type of crude oil. Thus, heavy oil is a type of crude oil that is different from conventional crude oil insofar the flow properties are reduced and a heavy oil is much more difficult to recover from the subsurface reservoir. These materials have a high viscosity (and low API gravity) relative to the viscosity (and API gravity) of conventional crude oil, and recovery of heavy oil usually requires thermal stimulation of the reservoir.

The definition of heavy oil is usually based on the API gravity or viscosity, but the definition is quite arbitrary. Although there have been attempts to rationalize the definition based upon viscosity, API gravity, and density, such definitions based on physical properties are inadequate and a more precise definition should involve some reference to the recovery method.

However, in a very general sense (and not in any sense meant to indicate classification of heavy oil), the term heavy oil is often applied to a crude oil that has a gravity $<20^\circ$ API and usually, but not always, a sulfur content higher than 2% w/w. Furthermore, in contrast to conventional crude oil, heavy oil is darker in color and may even be black. The term heavy oil has also been arbitrarily used to describe the heavy oil that requires thermal stimulation of

recovery from the reservoir and (albeit incorrectly) the bitumen in bituminous sand (tar sand, oil sand) formations from which the highly viscous bituminous material is recovered by a mining operation.

Crude oil varies widely in composition, and variations of the composition of heavy oil add further complexity to the use of these feedstocks in the production of liquid fuels. The variations in composition are generally reflected in variations in the API gravity, viscosity, and the potential for coke formation in thermal process, to mention only three of the affected properties. In addition to the organic constituents, there are also metal-containing constituents (notably those compounds that contain vanadium and nickel) which usually occur in the more viscous crude oil in amounts up to several hundred parts per million.

Physical methods of fractionation of crude oil and heavy oil can be achieved to produce four bulk generic fractions: saturates aromatics, resins, and asphaltenes. The relative amounts of these fractions have often been equated to the behavior of crude oil or heavy oil feedstocks during recovery and refining.

Conversion Pathways

Energy conversion of organic materials can proceed along three main pathways: (i) thermochemical conversion, (ii) biochemical conversion, and (iii) physicochemical conversion. Currently, all three pathways are utilized to varying degrees with fossil fuel feedstocks.

Thermochemical conversion processes include the typical processes such as combustion, gasification, and pyrolysis.

Biochemical conversion processes include aerobic conversion (i.e., composting), anaerobic decomposition or digestion (which occurs in landfills and controlled reactors or digesters), and anaerobic fermentation (for example, the conversion of sugars from hydrolyzed cellulose and hemicellulose by ethanol-producing yeasts and recombinant bacteria. Physicochemical conversion involves the physical and chemical synthesis of products from feedstocks (for example, biodiesel).

Biochemical conversion proceeds at lower temperatures and lower reaction rates. Higher moisture feedstocks are generally good candidates for biochemical processes. Thermochemical conversion is characterized by higher temperatures and faster conversion rates. It is best suited for lower moisture feedstocks. For biomass feedstocks, the lignin fraction currently cannot be converted biochemically, although research is investigating lignin fermentation processes. On the other hand, thermochemical routes can convert the entire organic portion of suitable feedstocks. The inorganic fraction (ash) of a feedstock does not contribute significantly to the energy products but does participate in important ways including fouling of high temperature equipment, increased nutrient (e.g., K and P) loading in facility wastewater treatment and disposal, and in some cases by providing marketable co-products or adding disposal cost. Inorganic constituents may also be catalytic for some of the conversion reactions.

Physicochemical conversion involves the physical and chemical synthesis of products from feedstocks and is primarily associated with the transformation of fresh or used vegetable oils, animal fats, greases, tallow, and other suitable feedstocks into liquid fuels or biodiesel.

See also: Conversion Processes, Biochemical Platform, Thermochemical Platform.

Conversion Processes – Biochemical

Biochemical conversion of biomass is completed through alcoholic fermentation to produce liquid fuels and anaerobic digestion or fermentation, resulting in biogas. Alcoholic fermentation of crops such as sugarcane and maize (corn) to produce ethanol for use in internal combustion engines has been practiced for years with the greatest production occurring in Brazil and the United States, where ethanol has been blended with gasoline for use in automobiles. With slight engine modifications, automobiles can operate on ethanol alone.

Anaerobic digestion of biomass has been practiced for almost a century, and is popular in many developing countries such as China and India. The organic fraction of almost any form of biomass, including sewage sludge, animal wastes, and industrial effluents, can be broken down through anaerobic digestion into methane and carbon dioxide.

This biogas is a reasonably clean burning fuel which can be captured and put to many different end uses such as cooking, heating, or electrical generation.

Fermentation plants producing biogas are in routine use, ranging from farms to large municipal plants. As feedstock, they use manure, agricultural residues, urban sewage, and waste from households, and the output gas is typically 64% methane. The biomass conversion process is accomplished by a large number of different agents, from the microbes decomposing and hydrolyzing plant material, over the acidophilic bacteria dissolving the biomass in aquatic solution, and to the strictly anaerobic methane bacteria responsible for the gas formation. Operating a biogas plant for a period of some months usually makes the bacterial composition stabilize in a way suitable for obtaining high conversion.

The photosynthetic production of gas (e.g., hydrogen) employs microorganisms such as cyanobacteria, which have been genetically modified to produce pure hydrogen rather than the metabolically relevant substances. The conversion efficiency from sunlight to hydrogen is small, usually under 0.1%, indicating the need for large collection areas.

If the bacteria are modified to produce maximum hydrogen, their own growth and reproduction are quenched. Presumably, there has to be made a compromise between the requirements of the organism and the amount of hydrogen produced for export, so that replacement of organisms (produced at some central biofactory) does not have to be made at frequent intervals. The implication of this is probably an overall efficiency lower than 0.05%.

See also: Aerobic Digester, Anaerobic Digester, Digesters.

Conversion Processes – Biomass Properties

Each type of biomass has its own specific properties which determine performance as a feedstock in gasification plants. The most important properties relating to gasification are (i) moisture content, (ii) mineral content leading to ash production, (iii) elemental composition, (iv) bulk density and morphology, and (v) volatile matter content.

The moisture content of biomass is defined as the quantity of water in the material expressed as a percentage of the weight of the material. For processes like gasification, preference is given to relative dry biomass feedstocks because a higher-quality gas is produced, i.e., higher heating value, higher efficiency, and lower tar levels. Natural drying is cheap but requires long drying times. Artificial drying is more expensive but also more effective. In practice, artificial drying is often integrated with the gasification plant to ensure a feedstock of constant moisture content. Waste heat from the engine or exhaust can be used to dry the feedstock.

Ash content (which represents an inorganic content) of biomass is the inorganic oxides that remain after complete combustion of the feedstock. The amount of ash between different types of feedstocks differs widely (0.1% for wood up to 15% for some agricultural products) and influences the design of the reactor, particularly the ash removal system. The chemical composition of the ash is also important because it affects the melting behavior of the ash. Ash melting can cause slagging and channel formation in the reactor. Slag can ultimately block the entire reactor.

The elemental composition of the biomass feedstock is important with regard to the heating value of the gas and to the emission levels. The production of nitrogen and sulfur compounds is generally small in biomass gasification because of the low nitrogen and sulfur content in biomass.

The bulk density refers to the weight of material per unit of volume and differs widely between different types of biomass. Together with the heating value, it determines the energy density of the gasifier feedstock, i.e. the potential energy available per unit volume of the feedstock. Biomass of low bulk density is expensive to handle, transport, and store. Apart from handling and storing behavior, the bulk density is important for the performance of the biomass as a fuel inside the reactor: a high void space tends to result in channeling, bridging, incomplete conversion, and a decrease in the capacity of the gasifier. The bulk density varies widely (100 to 1,000 kg/m³) between different biomass feedstocks not only because of the character of the biomass but also as a result of the way the biomass comes available (chips, loose, baled).

The amount of volatile products (volatile matter content) has a major impact on the tar production levels in gasifiers. Depending on the gasifier design, the volatile matter leaves the reactor at low temperatures (updraft gasifiers) or passes through a hot incandescent oxidation zone (downdraft gasifiers) where it is thermally cracked. For biomass materials, the volatile matter content varies between 50 and 80%.

Feedstock preparation is required for almost all types of biomass materials because of large variety in physical, chemical, and morphological characteristics. The degree to which any specific pretreatment is desirable will depend upon the gasifier. For example, capacity and type of reactor (downdraft gasifiers are stricter to uniform fuel specifications than updraft gasifiers) are important aspects of biomass gasification.

Sizing of the feedstock may be necessary as different sizes are specified for different types of gasifiers. For small-scale fixed bed gasifiers, cutting and/or sawing of wood blocks is the preferred form of fuel preparation. Chipped wood is preferred for larger-scale applications. The size range of chips can be chosen by screening such that the fuel is acceptable for a specific gasifier type. For medium- and large-scale fixed bed gasifiers, wood chips from forestry or wood processing industries are produced by crushers, hammer mills, shredders, and/or mobile chippers (particularly for thinnings from landscape conservation activities). Most of these sizing apparatus are provided with a screen. Dependent on the feedstock morphology and characteristics (hardness), the throughput or capacity varies considerably.

Drying of the biomass fuel is advisable if fresh wet materials (moisture content 50-60% on wet basis) are to be gasified. Lowering the moisture content of the feedstock is associated with a better performance of the gasifier. Utilizing the exhaust gases from an internal combustion engine is a very efficient way to do so. The sensible heat in engine exhaust is sufficient to dry biomass from 70% down to 10%. Rotary kilns are the most applied dryers. The energy costs of drying are high, but these can be outweighed by the lower downstream gas cleaning requirements for dried feed.

Densification, such as briquetting or pelletization, is an important technique to densify biomass materials for increasing the particle size and bulk density. The reasons for biomass include (i) densified biomass is less expensive to transport, (ii) densified products are easier to store and handle, and (iii) densification enables certain biomass feedstocks to be gasified in a specific gasifier.

The calorific value of the gas is the prime factor for power generation – the higher the value, the better. Hence, the availability in the gas of any compounds that increase calorific value is generally welcomed – product gas, which contains carbon monoxide (CO), hydrogen (H_2), and various hydrocarbon derivatives [methane (CH_4), ethylene (C_2H_4), ethane (C_2H_6), tars, and chars]. The presence of inert components [water (H_2O), carbon dioxide (CO_2), and nitrogen (N_2)] is also acceptable, provided it is kept within certain limits.

Environmental concerns include disposal of associated tars and ashes, particularly for the fluidized bed reactors, where these substances must be separated from the flue gas stream (in contrast to the pyrolysis plants, where most tar and ash deposit at the bottom of the reactor). Concerns over biomass transportation are similar to those mentioned above for fermentation, and a positive fertilizer effect can also in many cases be derived from the gasification residues.

Biomass ash also has the potential to be used as a clarifying agent in water treatment, as a wastewater adsorbent, as a liquid waste adsorbent, as a hazardous waste solidification agent, as a lightweight fill for roadways, parking areas, and structures, as asphalt mineral filler, or as a mine spoil amendment.

Conversion Processes – Combustion

Combustion offers the most direct route for energy recovery, and is an effective means of utilizing the total energy content of whole wood and other biomass. Technology for the combustion of carbonaceous feedstocks is well developed and feasible.

Gasification results in only a partial oxidation of the carbon constituent. Much of the calorific value of the original fuel leaves the gasifier in the form of chemical energy in carbon monoxide, methane, and hydrogen.

In combustion, air containing sufficient oxygen to completely oxidize the hydrocarbon is used. The resulting gas (flue gas) is essentially all carbon dioxide, water vapor, and diluent nitrogen, and has no calorific value. The energy of the original fuel leaves the system as sensible heat that can be used for steam generation and, if required, electricity generation.

Thus, combustion offers a practical means for recovering the energy in biomass materials, using currently available technology.

However, due to the large land area over which biomass must be harvested, the seasonal nature of the supply, and the large volume of material to be transported and stored, the reliable provision of biomass to a large combustion plant can present considerable problems.

Conversion Processes – Gasification

Gasification, a thermal conversion process, occurs through the thermal decomposition of biomass with the help of an oxidant such as pure oxygen or oxygen-enriched air to yield a combustible gas such as synthesis gas rich in carbon monoxide and hydrogen. The synthesis gas is post-treated, by steam reforming or partial oxidation, to convert the hydrocarbon derivatives produced by gasification into hydrogen and carbon monoxide. The carbon monoxide is then put through the shift process to obtain a higher fraction of hydrogen, by carbon dioxide removal and methanation or by pressure swing adsorption.

In the gasification process, one or more reactants, such as oxygen, steam, or hydrogen, are introduced into the system. These chemical reactants combine with solid carbon at the higher gasification temperatures, so increasing the gas yield while consuming char. The amount of char by-product remaining on gasification is in fact essentially zero with biomass materials, while the small quantity of tars and oils evolved may be recycled to extinction. The introduced reactants also enter into gas phase reactions which, together with the shift in equilibrium and the change in relative reaction rates at the higher temperatures, results in a significantly better-quality gas than that obtained on pyrolysis. Important distinctions between pyrolysis and gasification are therefore the improved gas yield and the elimination of solid and liquid by-products.

One major advantage with gasification is the wide range of biomass resources available, ranging from agricultural crops, and dedicated energy crops to residues and organic wastes. The feedstock might have a highly various quality, but still the produced gas is quite standardized and produces a homogeneous product. This makes it possible to choose the feedstock that is the most available and economic at all times.

The air-blown direct gasifiers operated at atmospheric pressure and used in power generation – fixed bed updraft and downdraft and fluidized bed bubbling and circulating – are not suitable for biomass-to-liquids production. In addition, downdraft fixed bed gasifiers face severe constraints in scaling and are fuel inflexible, being able to process only fuels with well-defined properties. Updraft fixed bed gasifiers have fewer restrictions in scaling, but the produced gas contains a lot of tars and methane.

Fluidized bed gasifiers generally do not encounter limitations in scaling and are more flexible concerning the particle size of fuels. Nevertheless, they still have limited fuel flexibility, due to a risk of slagging and fouling, agglomeration of bed material, and corrosion. The operating temperatures of air-blown fluidized bed gasifiers are therefore kept relatively low (800 to 1,000°C, 1,470 to 1,830°F), which implies incomplete decomposition of feedstocks, unless long residence times are used. Fluidized bed gasifiers (especially the bubbling bed ones) tend to contaminate the product gas with dust. The oxygen-blown atmospheric or pressurized circulating fluidized bed gasifiers and the steam-blown gas or char indirect gasifiers are better solutions for biomass-to-liquids production. Both gasifying concepts significantly reduce the amount of nitrogen in the product gas. In the first case, it is achieved via substituting air with oxygen. In the second case, nitrogen ends up in the flue gas, but not in the product gas, because gasification and combustion are separated – the energy for the gasification is obtained by burning the chars from the first gasifier in a second reactor.

The gasification of biomass (such as, e.g., wood scrap) is a well-known process, taking place in pyrolysis (oxygen supply far below what is required for complete combustion, the fraction called equivalence ratio) or fluidized-bed type of reactors. Conditions such as operating temperature determine whether hydrogen is consumed or produced in the process. Hydrogen evolution is largest for near-zero equivalence ratios, but the energy conversion efficiency is highest at an equivalence ratio around 0.25. The hydrogen fraction (in this case typically some 30%) must be separated for most fuel-cell applications, as well as for long-distance pipeline-transmission. In the pyrolysis-type application, gas production is low and most energy is in the oily substances that must be subsequently reformed in order to produce significant amounts of hydrogen. Typical operating temperatures are around 850°C. An overall energy conversion efficiency of around 50% is attainable, with considerable variations. Alternate concepts use membranes

to separate the gases produced, and many reactor types use catalysts to help the processes to proceed in the desired direction, notably at a lower temperature (down to some 500°C, 930°F).

See also: Gasification of Biomass.

Conversion Processes - Pyrolysis

Pyrolysis is the thermal decomposition of materials in the absence of oxygen or when significantly less oxygen is present than required for complete combustion.

Pyrolysis dates back to at least ancient Egyptian times when tar for caulking boats and certain embalming agents were made by pyrolysis. In the 1980s, researchers found that the pyrolysis liquid yield could be increased using fast pyrolysis where a biomass feedstock is heated at a rapid rate and the vapors produced are also condensed rapidly.

Pyrolysis is the basic thermochemical process for converting biomass to a more useful fuel. Biomass is heated in the absence of oxygen, or partially combusted in a limited oxygen supply, to produce a hydrocarbon-rich gas mixture, an oil-like liquid, and a carbon-rich solid residue. The pyrolysis of treatment of biomass to produce hydrocarbon derivatives has been studied since the 1930s, and while relatively simple to perform, typically, such processes are non-selective, producing a wide range of products. Thus, direct thermochemical conversion processes including pyrolysis to produce fuels from biomass are also possible resulting in the production of gaseous products (gaseous fuels), liquid products (liquid fuels), and charcoal (solid fuels).

The pyrolysis of biomass is a thermal treatment that results in the production of charcoal, liquid, and gaseous products. Thus, biomass is heated in the absence of air and breaks down into a complex mixture of liquids, gases, and a residual char. If wood is used as the feedstock, the residual char is what is commonly known as charcoal. With more modern technologies, pyrolysis can be carried out under a variety of conditions to capture all the components, and to maximize the output of the desired product be it char, liquid, or gas.

The liquid fraction of the pyrolysis products consists of two phases: an aqueous phase containing a wide variety of organo-oxygen compounds of low molecular weight and a non-aqueous phase containing insoluble organics of high molecular weight. This phase is called tar and is the product of greatest interest. The ratios of acetic acid, methanol, and acetone of the aqueous phase were higher than those of the non-aqueous phase. The point where the cost of producing energy from fossil fuels exceeds the cost of biomass fuels has been reached. With few exceptions, energy from fossil fuels will cost more money than the same amount of energy supplied through biomass conversion.

Wood contains 80% or more of volatile organic matter that may be recovered as a gas and tar on pyrolysis. Pyrolysis of wood was at one time used for obtaining creosote oils as well as acetic acid (wood vinegar) and some methanol (wood spirits). The gases evolved (hydrogen, methane, carbon monoxide, and carbon dioxide) had no value for illumination purposes and were used to supply the heat for the pyrolysis. Gasification of wood may be used to produce either a low- or a medium-heat content gas if a gaseous fuel is desired, or a synthesis gas that can be converted to liquid fuels using one of the indirect liquefaction processes. Gasification followed by a synthesis step is expected to yield a higher-quality liquid than can be obtained by pyrolysis.

The relative quantity of char, tars, and gases evolved on pyrolysis is strongly dependent on the feedstock, then on the rate of heating and the final temperature attained. Slow-heating, low temperature pyrolysis favors char yields. After the initial decomposition, subsequent coking and cracking reactions can result in a char that contains oxygen and hydrogen in addition to the carbon.

Apart from char and water, some tars and gases are always produced. The watery distillate evolved from wood at 160 to 175°C (320 to 345°F) is called pyroligneous acid and contains 5 to 10% acetic acid and 1.5 to 3% methanol. This used to be the source of methanol when it was produced by the destructive distillation (pyrolysis) of wood.

The higher boiling tar fraction produced at higher temperatures is more important as a source of liquid fuels. It contains aromatic hydrocarbon derivatives and creosote oil evolved from the lignin, as well as aliphatic compounds. The creosote oil, which consists of high-molecular-weight phenols, used to be considered the most valuable constituent of the tar fraction, in part due to its potential for resin manufacture. As a whole, the tar fraction is a viscous, highly oxygenated oil that is unstable and corrosive.

The pyrolysis option for biomass is attractive because solid biomass and wastes can be readily converted into liquid products. These liquids, as crude bio-oil or slurry of charcoal of water or oil, have advantages in transport, storage, combustion, retrofitting, and flexibility in production and marketing.

The mechanism of the pyrolysis of biomass is proposed to involve heat variations, associated with the thermal degradation reactions, which affect the pyrolysis route. Several endothermic and/or exothermic peaks for biomass pyrolysis are indicated. Accordingly, cellulose pyrolysis is endothermic but lignin pyrolysis is exothermic.

However, the pyrolysis of biomass is more complex than originally believed and the general changes that occur during biomass pyrolysis are: (i) heat transfer from a heat source, to increase the temperature inside the fuel, (ii) the initiation of primary pyrolysis reactions at this higher temperature releases volatiles and forms char, (iii) the flow of hot volatiles toward cooler solids results in heat transfer between hot volatiles and cooler unpyrolyzed fuel, (iv) condensation of some of the volatiles in the cooler parts of the fuel, followed by secondary reactions, can produce tar, (v) autocatalytic secondary pyrolysis reactions proceed while primary pyrolytic reactions simultaneously occur in competition, and (vi) further thermal decomposition, reforming, water gas shift reactions, radical recombination, and dehydrations can also occur, which are a function of the residence time/temperature/pressure profile of the process.

The chemical structure of xylan is variable, but for the xylan in hardwood, the structure can be shown as:

Also, the pyrolysis of the pyroligneous acid produces 50% methanol, 18% acetone, 7% esters, 6% aldehydes, 0.5% ethyl alcohol, 18.5% water, and small amounts of furfural. The composition of the water-soluble products was not ascertained but it has been reported to be composed of hydrolysis and oxidation products of glucose such as acetic acid, acetone, simple alcohols, aldehydes, and sugars.

See also: Pyrolysis.

Conversion Processes – Thermal

In keeping with crude oil refining technology, conversion processes as used in the biofuels industry change the size and/or structure of feedstock constituents.

Biomass conversion is accomplished through the use of several distinct processes which include both biochemical conversion and thermal conversion to produce gaseous, liquid, and solid fuels which have high energy contents, are easily transportable, and are therefore suitable for use as commercial fuels.

Thermal conversion offers an effective means for the recovery or conversion of the energy content of wood and other lignocellulosic biomass. Wood and many other similar types of biomass which contain lignin and cellulose (agricultural wastes, cotton gin waste, wood wastes, peanut hulls etc.) can be converted through thermochemical processes into solid, liquid, or gaseous fuels. Pyrolysis, used to produce charcoal since the dawn of civilization, is still the most common thermochemical conversion of biomass to commercial fuel.

Direct conversion processes, i.e., combustion, of biomass encounters the same problems as those in case of coal or other solid fuels. The conversion of biomass into other useful forms such as synthetic gas or liquid fuels is considered as an alternative way to make use of biomass energy. Gasification is an effective and well-known technology which has been applied to coal, but the technology developed for coal is not exactly suited to biomass utilization because of the different physical and chemical properties between coal and biomass.

Copper Sweetening Process

The copper sweetening process is a process for the purification of liquid fuels which involves oxidation of mercaptans to disulfides by oxygen in the presence of cupric chloride. The oxidizing power of cupric (Cu^{2+}) salts is also utilized to convert mercaptans directly into disulfides; free sulfur is not employed, and polysulfides are not obtained. The process employs cupric chloride in the presence of strong salt solutions, which are generally made up by dissolving copper sulfate in an aqueous solution of sodium chloride.

The cuprous chloride (CuCl) is soluble in the salt solution, and there is no precipitation. Under operating conditions, a certain amount of copper is retained by the sweetened liquid fuel, probably as cuprous mercaptides or cuprous chloride-olefin addition products, but these can be removed by washing the material with aqueous sodium sulfide. Air blowing the cuprous chloride solution, after or during the sweetening operation, regenerates the cupric chloride. The copper chloride solution may be employed as such, or the sour fraction may be percolated through a porous mass saturated with the treating agent. Alternatively, the liquid fuel may be mixed with a solid carrier for the reagent, dispersed as a slurry.

Three methods of mechanical application of the copper chloride are used. If air will not cause the fuel to change color or form gum, a fixed-bed process may be used in which the sour material is passed through beds of an adsorbent that have been impregnated with cupric chloride. Air continuously regenerates the cupric chloride almost simultaneously with the sweetening reaction.

In the solution process, a solution of cupric chloride is continuously mixed in a centrifugal pump with the sulfur-containing fuel. The mixture then enters a settling tank where the spent treatment solution separates from the liquid, and the treatment solution is withdrawn to a tank where blowing with air regenerates cupric chloride. The slurry process makes use of clay or a similar material impregnated with cupric chloride. The clay is mixed with a small amount of, say, naphtha to form a slurry, which is pumped into the sour naphtha stream. Air or oxygen gas is added with the sour stream and continuously regenerates the cupric chloride. The treated material and clay slurry flow into a settling tank and separate, and then the clay slurry is recycled.

Cord

A cord is a stack of wood comprising 128 ft^3 (3.62 m^3); standard dimensions are $4 \times 4 \times 8 \text{ ft}$, including air space and bark. One cord contains approximately 1.2 U.S. tons (oven-dry and equal to 2,400 lb). The name "cord" probably comes from the use of a cord or string to measure it.

Wood is an organic natural material, a composite of cellulose fibers embedded in a matrix of lignin. In the strict sense, wood is produced as secondary xylem in the stems of trees (and other woody plants) and has a support function, enabling woody plants to reach large sizes or to stand up for themselves. However, wood may also refer to other plant materials with comparable properties, and to material engineered from wood, or wood chips or fiber.

A cord of hard wood, such as ash or maple, is approximately equal in heating value to one ton of bituminous coal; soft woods, such as pine and poplar, have less than half this amount.

Firewood quantities are sometimes difficult to estimate. The official measurement of firewood is a "cord." To help you make an accurate estimate, here is how some common units of firewood measurement compare to the full cord.

Other terms, such as face cord, stove cord, or furnace cord, are sometimes used to describe a stack of wood measuring 4 ft. high, 8 ft. long with a piece length shorter than 4 ft. A common firewood piece length is 16 in., or one-third of a full cord, but other lengths are also available. Other non-legal definitions of firewood volume include

standing cord, kitchen cord, running cord, face cord, fencing cord, country cord, long cord, and rick. As none of these terms is a legally defined measurement, they are all subject to local variations. The only correct measurement of firewood and pulpwood is the cord and fractions thereof (e.g., half-cord, quarter-cord).

Cordgrass

Spartina (*Spartina alterniflora*, cordgrass, cord-grass) contains 14 species, native to the coasts of the Atlantic Ocean in western and southern Europe, northwest and southern Africa, the Americas, and the southern Atlantic Ocean islands. One or two species also occur on the North American Pacific coast and in freshwater habitats inland in the Americas. The highest species diversity is on the east coasts of North America and South America, particularly Florida. They form large, often dense colonies, particularly on coastal salt marshes, and grow quickly and can vary in size from one to six feet tall.

Cordgrasses are perennial plants and spread by means of rhizomes to form clumps and mats which help to reduce erosion and reclaim land from the sea, and the root system of saltmarsh cordgrass helps stabilize the marsh mud. Taller than salt meadow cordgrass and with flat, smooth blades, saltmarsh cordgrass grows along the sides of guts (marsh creeks) and in places flooded by the tides. Cordgrasses are able to survive in areas flooded by salt water because of the regulatory system they have developed that excretes unneeded salt on the leaf edges.

Cordgrasses are expected to be able to produce good yields of biomass in poor soil conditions.

Coriolis Force

The Coriolis force (sometimes called the Coriolis effect) is named after the French mathematician Gaspard-Gustave de Coriolis (1792–1843). The principle behind the Coriolis force is that because Earth rotates, any movement in the Northern Hemisphere is diverted to the right, if observed from a fixed position on the ground. In the Southern Hemisphere, the movement is to the left. This means that wind tends to rotate counterclockwise around low-pressure areas in the Northern Hemisphere and clockwise in the Southern Hemisphere.

The self-rotation of the Earth is an important factor to affect wind direction and speed. The Coriolis force, which is generated from the Earth's self-rotation, deflects the direction of atmospheric movements. In the north atmosphere, wind is deflected to the right and in the south atmosphere to the left. The Coriolis force depends on the latitude of the Earth – the force is zero at the equator and reaches maximum values at the poles. In addition, the amount of deflection on wind also depends on the wind speed; slowly blowing wind is deflected only a small amount, while stronger wind is deflected more.

In large-scale atmospheric movements, the combination of the pressure gradient due to the uneven solar radiation and the Coriolis force due to the self-rotation of the Earth causes the single meridional cell to break up into three convectional cells in each hemisphere: the Hadley cell, the Ferrel cell, and the Polar cell, and each cell has its own characteristic circulation pattern.

In the Northern Hemisphere, the Hadley cell circulation lies between the equator and north latitude 30°, dominating tropical and sub-tropical climates. The hot air rises at the equator and flows toward the North Pole in the upper atmosphere. This moving air is deflected by Coriolis force to create the northeast trade winds.

At approximately north latitude 30°, the Coriolis force becomes so strong to balance the pressure gradient force. As a result, the winds are deflected to the west. The air accumulated at the upper atmosphere forms the subtropical high-pressure belt and thus sinks back to the earth's surface, splitting into two components: one returns to the equator to close the loop of the Hadley cell; another moves along the surface of the Earth toward the North Pole to form the Ferrel Cell circulation, which lies between north latitude 30° and 60°. The air circulates toward the North Pole along the surface of the Earth until it collides with the cold air flowing from the North Pole at approximately north latitude 60°. Under the influence of the Coriolis force, the moving air in this zone is deflected to produce westerly winds. The Polar cell circulation lies between the North Pole and north latitude 60°. The cold air sinks down at the

North Pole and flows along the surface of the Earth toward the equator. Near north latitude 60° , the Coriolis effect becomes significant to force the airflow to southwest.

The Coriolis force does not explain wind direction in all places at all times. Local factors also determine the speed and direction of the wind. An example is a sea breeze. Land masses warm faster in the sun than water does. This means that the air over land expands and rises faster than the air over the sea. At night, the process is reversed, and wind tends to blow offshore, that is, from land out to sea. Mountain ranges also play tricks with the wind, diverting it in different directions. amounts of electricity for local use.

In summary, in the Northern Hemisphere, the Coriolis force turns the winds to the right. In the Southern Hemisphere, the Coriolis force turns the winds to the left. From 30° latitude to 60° latitude, the Ferrel Cell takes over and produces prevailing westerly winds at the surface within these latitudes.

Corn

Maize (corn) is a grass domesticated by indigenous peoples in Mesoamerica in prehistoric times. Native Americans cultivated it in numerous varieties throughout the Americas. After European contact with the Americas in the late 15th and early 16th centuries, explorers and traders carried maize back to Europe and introduced it to other countries through trade. Its use spread to the rest of the world.

Maize is the most widely grown crop in the Americas. Hybrid maize, because of its high-grain yield as a result of heterosis, is preferred by farmers over conventional varieties. While some maize varieties grow up to 23 feet tall, most commercially grown maize has been bred for a standardized height of approximately 8 feet). Sweet corn is usually shorter than field-corn varieties.

See also: Corn Stalks And Wheat Straw.

Corn Ethanol

Corn ethanol is ethanol produced from corn biomass and is the main source of ethanol fuel in many countries. It is debatable whether the production and use of corn ethanol results in lower greenhouse gas emissions than gasoline. There are two main types of corn ethanol production: (i) dry milling and (ii) wet milling which differ in the initial grain treatment method and co-products.

In the dry milling process, the entire corn kernel is ground into flour (often referred to as mash) which is then slurried by adding water. Enzymes are added to the mash to hydrolyze the starch into simple sugar derivatives. Ammonia is added to control the pH and as a nutrient for the yeast, which is added later. The mixture is processed at high temperatures to reduce the levels of the bacteria after which the mash is transferred and cooled in fermenters. Yeast is then added which causes the sugars to ferment into ethanol and carbon dioxide. The entire process takes approximately two days (40 to 50 hours), during which time the mash is kept cool and agitated to promote the activity of the yeast. The ethanol is purified through a combination of distillation and dehydration to create fuel ethanol. The mash is then transferred to distillation columns, where the ethanol is removed from the stillage. The ethanol is dehydrated to near-pure alcohol (200 proof alcohol) using a molecular sieve system. A denaturant such as gasoline is added to render the product undrinkable after which the product is then ready to ship to gasoline retailers or terminals. The remaining stillage is processed into a livestock feed (known as distiller's dried grains and solubles, DDGS). The carbon dioxide released from the process is used to carbonate beverages and for manufacturing cry ice (solid carbon dioxide).

In the wet milling process, the corn grain is separated into components by steeping it in dilute sulfuric acid for 24 to 48 hours. The slurry mix then passed through a series of grinders to separate out the corn germ. The remaining components of fiber, gluten and starch, and starch are segregated using screen, hydrocyclone, and centrifugal separators. The corn starch and remaining water can be fermented into ethanol through a similar process as dry milling, dried and sold as modified corn starch, or made into corn syrup. The gluten protein and steeping liquor are dried to

make a corn gluten meal that is sold to the livestock industry. The heavy steep water is also sold as a feed ingredient and used as an alternative to salt in the winter months. Corn oil is also extracted and sold.

See also: Corn Oil, Ethanol From Corn.

Corn Oil

Corn oil (maize oil) is oil extracted from the germ of corn (maize). The main use of corn oil is in cooking, where the high smoke point makes refined corn oil a valuable frying oil. Corn oil is also a feedstock used for biodiesel.

Typically, corn oil is expeller-pressed then solvent-extracted using a solvent such as hexane or 2-methyl pentane (isohexane) after which the solvent is evaporated from the corn oil, recovered, and re-used. After extraction, the corn oil is then refined by degumming and/or alkali treatment, both of which remove phosphatide derivatives. Alkali treatment also neutralizes free fatty acids and removes color (bleaching). The final steps in refining corn oil include the removal of wax derivatives, and deodorization by steam distillation of the oil at 232 to 260°C (450 to 500°F) under a high vacuum.

See also: Corn Ethanol.

Corn Stalks and Wheat Straw

From the agricultural sector, the major cellulosic resources are corn stalks and wheat straw. Both are left in the field after the grain is harvested in much of the U.S. While a portion of this residue does have a value in maintaining soil quality and crop productivity, in some higher yield areas of the United States, there is an excess of residue produced that could be beneficially removed. It is important to use this resource in a way that is environmentally and economically sound and that supplies the needs of biorefineries in terms of cost, quality, and consistency.

Corn stalks and wheat straws are the two agricultural residues produced in the largest quantities. However, many other residues such as potato and beet waste may be prevalent in some regions. In addition to quantity, it is necessary to consider density and water content (which may restrict the feasibility of transportation) and seasonality which may restrict the ability of the conversion plant to operate on a year-round basis. Facilities designed to use seasonal crops will need adequate storage space and should also be flexible enough to accommodate renewable feedstocks such as wood residues or other wastes in order to operate year-around. Some agricultural residues need to be left in the field in order to increase tilth (the state of aggregation of soil and its condition for supporting plant growth and to reduce erosion), but some residues such as corncobs can be removed and converted without much difficulty.

Similar to herbaceous crops, straw usually has lower moisture content than woody biomass. Conversely, it has a lower calorific value, bulk density, ash melting point and higher content of ash, and problematic inorganic component such as chlorine, potassium, and sulfur, which cause corrosion and pollution. The last two drawbacks can be relatively easily overcome by leaving straw on the field for a while. In such a way, rainfall “washes” it naturally from a large part of potassium and chlorine. Alternatively, fresh straw can be directly shipped to the gasification plant, where it is washed by dedicated facilities at moderate temperatures (50 to 60°C, 122 to 140°F). Due to washing, the initially low moisture content of straw becomes higher in both cases and hence a mandatory drying is applied afterwards. In both cases also, the content of corrosive components is reduced, but not completely taken out. In order to decrease handling costs, straw and dedicated herbaceous energy crops are usually baled before being shipped to the gasification plant. The weight and the size of bales depend on the baling equipment and on the requirements of the gasification plant.

Corn-to-Ethanol Process

Fermentation of sugars to ethanol (Figure 1), using commercially available fermentation technology, provides a fairly simple, straightforward means of producing ethanol with little technological risk. The system modeled assumes that

the molasses are clarified, and then fermented via cascade fermentation with yeast recycle. The stillage is concentrated by multiple-effect evaporation, and a molecular sieve is used to dehydrate the ethanol.

For more than 150 years in the United States, corn refiners have been perfecting the process of separating corn into its component parts to create a myriad of value-added corn products. The corn wet milling process separates corn into its four basic components, viz., starch, germ, fiber, and protein. There are several basic steps involved to accomplish this corn refining and alcohol fermentation process.

The corn wet milling process separates corn into its four basic components: starch, germ, fiber, and protein. The basic steps to accomplish this process are as follows. First, the incoming corn is inspected and cleaned. Then, it is steeped for 30 to 40 hours to begin breaking the starch and protein bonds. The next step in the process involves a coarse grind to separate the germ from the rest of the kernel. The remaining slurry consisting of fiber, starch, and protein is finely ground and screened to separate the fiber from the starch and protein. The starch is separated from the remaining slurry in hydrocyclones, after which the starch can be converted to syrup or it can be made into several other products through a fermentation process.

See also: Corn Ethanol, Wet Milling Process.

Corrosion

One aspect of energy production from any source is the potential of corrosion of the process equipment. Corrosion is a diffusion-controlled process that occurs on exposed surfaces. As a result, methods to reduce the activity of the exposed surface, such as passivation, can increase a material's corrosion resistance.

In the corrosion process, a refined metal is converted to a more stable form, such as its oxide, hydroxide, or sulfide. It is the gradual destruction of materials (usually metals) by chemical and/or electrochemical reaction with the environment, but the mechanism of corrosion is not always predictable. The corrosion process degrades the useful properties of materials and structures including strength, appearance, and permeability to liquids and gases. Corrosion can be concentrated locally to form a pit or crack, or it can extend across a wide area more or less uniformly corroding the surface.

In the most common use of the word, this means electrochemical oxidation of metal in reaction with an oxidant such as oxygen or sulfur. Rusting, the formation of iron oxides, is a well-known example of electrochemical corrosion. This type of damage typically produces oxides or salts of the original metal, and may result in a distinctive coloration of the metal surface. Corrosion can also occur in materials other than metals, such as ceramics or polymers, although in this context, the term degradation is more common.

See also: Corrosion by Fuel Ash.

Corrosion by Fuel Ash

One particular aspect of corrosion that deserves attention is the presence of alkali metals that occur in biomass and the presence of these metals in the ash after biomass combustion.

Fuel ash corrosion of components in process furnaces, utility boilers, and other equipment where fuels with a high metal content are fired is due to the effects of vanadium and sodium contained in the fuel. These metals are found in the form of organometallic complexes called porphyrins which are concentrated during the refining cycle in heavy residual fuels. In addition to these organometallic complexes, sources of additional metallic salts such as spent caustic and entrained salt in the crude are also concentrated in the heavy fuels. These salts act synergistically with the vanadium compounds present and can cause accelerated corrosion of metals and refractories in utility boiler and process furnaces when firing these types of fuels.

Sodium plus vanadium in the fuel in excess of 100 ppm can be expected to form fuel ashes corrosive to metals by fuel oil ashes.

Counter-Current Fixed Bed Gasifier

The counter-current fixed bed gasifier (up draft gasifier) consists of a fixed bed of carbonaceous fuel (such as biomass) through which the gasification agent (steam, oxygen, and/or air) flows in counter-current configuration. The ash is either removed dry or as a slag. The slagging gasifiers require a higher ratio of steam and oxygen to carbon in order to reach temperatures higher than the ash fusion temperature. The nature of the gasifier means that the fuel must have high mechanical strength and must be non-caking so that it will form a permeable bed, although recent developments have reduced these restrictions to some extent. The throughput for this type of gasifier is relatively low. Thermal efficiency is high as the gas exit temperatures are relatively low. However, this means that tar and methane production is significant at typical operation temperatures, so product gas must be extensively cleaned before use or recycled to the reactor.

The major advantages of this type of gasifier are its simplicity, high charcoal burn-out, and internal heat exchange leading to low gas exit temperatures and high gasification efficiency. In this way also, fuels with a high moisture content (up to 50% w/w) can be used. However, high amounts of tar and pyrolysis products are produced because the pyrolysis gas is not lead through the oxidation zone. This is of minor importance if the gas is used for direct heat applications, in which the tar is burned. In case the gas is used for engines, gas cleaning is required, resulting in problems of tar-containing condensates.

See also: Gasification, Gasifiers.

Covered Lagoon Digester

A digester is a sealed container or tank, where the biological digestion of organic waste (such as animal manure) can occur and biogas is formed.

A covered lagoon digester, as the name suggests, consists of a manure storage lagoon with a cover. The cover traps gas produced during decomposition of the manure. This type of digester is the least expensive of the three.

Typically covered lagoons are used with flush manure management systems that discharge manure at 0.5 to 2% solids. The in-ground, earth, or lined lagoon is covered with a flexible or floating gas tight cover. They are not heated and considered ambient temperature digesters. Retention time is usually 30-45 days or longer depending on lagoon size. In climates that have elevated year round temperatures, such as southern and western United States, these digesters can produce stable, reduced-odor, nutrient-rich effluent for application on fields and crops; pathogen and weed seed reduction and produce biogas for farm energy use. Heat recovery from the biogas can be used to heat nurseries on swine farms and warm milking parlors on dairy farms. Large lagoons in hot climates may produce sufficient quantity, quality, and consistency of gas to justify use in an engine generator. In areas with cooler climates, waste digestion, odor control, and gas production will be less consistent and the low-quality gas may need to be flared off much of the year for odor control and greenhouse gas reduction.

Covering a manure storage lagoon is a simple form of digester technology suitable for liquid manure with less than 3% solids. For this type of digester, an impermeable floating cover of industrial fabric covers all or part of the lagoon. A concrete footing along the edge of the lagoon holds the cover in place with an airtight seal. Methane produced in the lagoon collects under the cover. A suction pipe extracts the gas for use. Covered lagoon digesters require large lagoon volumes and a warm climate. Covered lagoons have low capital cost, but these systems are not suitable for locations in cooler climates or locations where a high water table exists.

See also: Digester.

Cracking

Cracking is a thermal process by which the constituents of a feedstock are converted to lower molecular weight products. The term cracking applies to the decomposition of carbonaceous constituents (such as biomass to produce bio-oil) that is induced by elevated temperatures ($>350^{\circ}\text{C}$, $>660^{\circ}\text{F}$) whereby the higher molecular weight constituents of crude oil are converted to lower molecular weight products. Cracking reactions involve carbon-carbon bond rupture and are thermodynamically favored at high temperature. Two general types of reaction occur during cracking that can be illustrated by simple equations:

The decomposition of large molecules into small molecules (primary reactions):

Reactions by which some of the primary products interact to form higher molecular weight materials (secondary reactions):

or

Thermal cracking is a free radical chain reaction; a free radical is an atom or group of atoms possessing an unpaired electron. Free radicals are very reactive, and it is their mode of reaction that actually determines the product distribution during thermal cracking. Free radical reacts with a hydrocarbon by abstracting a hydrogen atom to produce a stable end product and a new free radical. Free radical reactions are extremely complex, and it is hoped that these few reaction schemes illustrate potential reaction pathways. Any of the preceding reaction types are possible, but it is generally recognized that the prevailing conditions and those reaction sequences that are thermodynamically favored determine the product distribution.

In the cracking process, the aromatic ring is considered fairly stable at moderate cracking temperatures (350 to 500°C , 660 to 930°F). Alkylated aromatics, like the alkylated naphthenes, are more prone to dealkylation than to ring destruction. However, ring destruction of the benzene derivatives occurs above 500°C (930°F), but condensed aromatics may undergo ring destruction at somewhat lower temperatures (450°C , 840°F).

Catalytic cracking is the thermal decomposition of carbonaceous materials in the presence of a catalyst. Catalytic cracking also results in production of the maximum amount of butenes and butanes (C_4H_8 and C_4H_{10}) rather than ethylene and ethane (C_2H_4 and C_2H_6).

Clay minerals are a family of crystalline aluminosilicate solids, and the acid treatment develops acidic sites by removing aluminum from the structure. The acid sites also catalyze the formation of coke, and Houdry developed a moving bed process that continuously removed the cooked beads from the reactor for regeneration by oxidation with air. Although thermal cracking is a free radical (neutral) process, catalytic cracking is an ionic process involving carbonium ions, which are hydrocarbon ions having a positive charge on a carbon atom. The formation of carbonium ions during catalytic cracking can occur by either of the following processes: (i) addition of a proton from an acid catalyst to an olefin or (ii) abstraction of a hydride ion (H^-) from a hydrocarbon by the acid catalyst or by another carbonium ion.

However, carbonium ions are not formed by cleavage of a carbon-carbon bond. In essence, the use of a catalyst permits alternate routes for cracking reactions, usually by lowering the free energy of activation for the reaction. The acid catalysts first used in catalytic cracking were amorphous solids composed of approximately 87% silica (SiO_2) and 13% alumina (Al_2O_3) and were designated low-alumina catalysts. However, this type of catalyst is now being replaced by crystalline aluminosilicates (zeolites) or molecular sieves. The first catalysts used for

catalytic cracking were acid-treated clays, formed into beads. In fact, clays are still employed as catalyst in some cracking processes.

See also: Thermal Decomposition.

Cropland

Croplands are those lands dedicated to the growth of crops. The total cropland includes five components: cropland harvested, crop failure, cultivated summer fallow, cropland used only for pasture, and idle cropland.

Currently, the term croplands is often used more specifically to include those lands that are used to grow crops that can be converted into biofuel.

Cropland pasture is land used for long-term crop rotation. However, some cropland pasture is marginal for crop uses and may remain in pasture indefinitely. This category also includes land that was used for pasture before crops reached maturity and some land used for pasture that could have been cropped without additional improvement.

Crops

Biomass currently provides varying proportions (depending upon the country) of the primary energy supply. Projections are that this proportion will need to increase dramatically to meet growing energy demand. Given a relatively fixed land base, the production of energy crops will compete with traditional agricultural and forestry uses of land. It is essential that agriculture and forestry work together to create integrated biomass production systems that landowners can use to help meet the growing energy demands of the United States. Producing fast-growing short rotation woody crops on agricultural lands is one such approach that shows considerable promise. When produced in integrated systems, short rotation woody crops combine the goals of sustainable forestry with those of sustainable agriculture at multiple temporal and spatial scales. In addition to using woody biomass for energy for power and heat generation via co-firing and gasification, woody crops with their high hemicellulose and cellulose content are well suited for biorefining to yield liquid fuels such as ethanol, methanol, distillable oil (sometimes referred to as pyrolysis oil or bio-oil), and other products, such as biodegradable plastics and specialty chemicals.

Crops are the annual or seasonal yield of any plant that is grown to be harvested as food, as livestock fodder, fuel, or for any other economic purpose in significant quantities. This category includes crop species as well as agricultural techniques related to cropping. There are many types of crops that are used for industrial purposes. For example, crops are grown and harvested for the sole purpose of making profit and feeding people, as they are grown in large amounts in a certain area suitable for growing crops. Crops have essentially many functions and benefit particularly for the *human animal*! The products from crops are not only used as primary source of human foods and animal feed, but also as source of timber, fibers, and biomass energy. In addition, crops also have an essential function to maintain ecological systems and natural environment. Most of crop production is used as foods, but in the last century (the 20th century), crops were also cultivated for non-food use – examples are pharmaceutical and nutritional products, chemical derivative products such as adhesive, paints, polymer, plastics, and industrial oils in forms of bio diesel, transmission fluids, and lubricants.

Many efforts have been carried out to grow crops for foods production in order to strengthen food security, and to alleviate the hunger and poverty particularly in developing countries. However, serious consideration should also be directed toward cultivation of crops for non-food use.

Thus, by definition, energy crops are plants grown specifically for use as a fuel. Although growing crops for fuel date from medieval times, in their modern form, energy crops are the most recent and innovative renewable energy option. Energy crops are important as a renewable energy technology because their use will produce a variety of economic, environmental, and energy benefits (Lago et al., 2019). Commercial energy crops are typically densely planted, high-yielding crop species where the energy crops will be burnt to generate power. Woody crops such as willow and poplar are widely utilized, as well as tropical grasses such as miscanthus and elephant grass (*Pennisetum purpureum*).

Grasses are usually herbaceous plants with narrow leaves growing from the base. They include the true grasses of the Poaceae (or Gramineae) family, as well as the sedges (Cyperaceae) and the rushes (Juncaceae). The true grasses include cereals, bamboo, and the grasses of lawns (turf) and grassland. Sedges include many wild marsh and grassland plants, and some cultivated ones such as water chestnut (*Eleocharis dulcis*) and papyrus sedge (*Cyperus papyrus*). Most of the interest in grass biomass tends to focus on economics, but there is a list of traits that should be considered and valued when evaluating a potential solid biomass energy source. These traits are beneficial to society in general, or impact the suitability of biomass for a farm operation.

If the carbohydrate content is desired for the production of biogas, whole-crops, such as maize, Sudan grass, millet, white sweet clover, and many others, can be made into silage after which they can be converted into biogas. On the other hand, crop residues are the residues remaining after crops have been harvested. Crop residues typically contain 40% w/w of the nitrogen (N), 80% w/w of the potassium (K), and 10% w/w of the phosphorus (P) applied to the soil in the form of fertilizer. If these residues are subjected to direct combustion for energy, only a small percentage of the nutrients is left in the ash.

The valuable portion of sugar and starch crops (in terms of biofuel production) is the stalks and leaves, which are composed mainly of cellulose. The individual six-carbon sugar units in cellulose are linked together in extremely long chains by a stronger chemical bond than exists in starch. In *starch crops*, most of the six-carbon sugar units are linked together in long, branched chains (*starch*). Yeast cannot use these chains to produce ethanol. The starch chains must be broken down into individual six-carbon units or groups of two units. The starch conversion process is relatively simple because the bonds in the starch chain can be broken in an inexpensive manner by the use of heat and enzymes, or by a mild acid solution.

Sugar crops include a variety of plants such as fodder beets, fruit crops, Jerusalem artichokes, sugar beets, sugar cane, and sweet sorghum. Interest in ethanol production from such agricultural crops has prompted the development of sugar crops that have not been cultivated on a widespread commercial basis in many countries. Preparation is basically a crushing and extraction of the sugars which the yeast can immediately use. But sugar crops must be dealt with fairly quickly before their high sugar and water content causes spoilage. Because of the danger of such spoilage, the storage of sugar crops is not practical.

As with starch, cellulose must be broken down into sugar units before it can be used by yeast to make ethanol. However, the breaking of the cellulose bonds is much more complex and costly than the breaking of the starch bonds. Breaking the cellulose into individual sugar units is complicated by the presence of lignin, a complex compound surrounding cellulose, which is even more resistant than cellulose to enzymatic or acidic pretreatment (Hwang and Obst, 2003). Because of the high cost of converting liquefied cellulose into fermentable sugars, agricultural residues (as well as other crops having a high percentage of cellulose) are not yet a practical feedstock source for small ethanol plants.

Crop residues (cobs, stems, leaves, in particular straw, and other plant matter) left in agricultural fields after harvest could potentially be used for solid biofuels production. Due to high energy content, straw is one of the best crop residues for solid biofuels. However, straw has several disadvantages – it has a higher ash content, which results in lower calorific value. In order to improve its bulk density, the straw is generally baled before transportation. Straw burning requires a specific technology, and there are four basic types of straw burners: (i) the burners that accept shredded, loose straw, (ii) the burners that use densified straw products such as pellets, briquettes or cubes, and straw logs, (iii) the burners for small, square bale of feedstock, and (iv) the burners for round bales of feedstock. To be suitable for heat and electricity production, straw should not have a large content of moisture, preferably not more than 20% as the moisture reduces the boiler efficiency. Also, straw color as well as straw chemistry should be considered before burning as it indicates the quality of the straw. Most crop residues are returned to the soil, and the humus resulting from their decomposition helps maintain soil nutrients, soil porosity, water infiltration, and storage, as well as reducing soil erosion.

Wood is the oldest fuel known to man. Burning wood rather than fossil fuels can reduce the carbon dioxide emissions responsible for global climate change. Wood fuel is carbon dioxide (CO₂)-neutral. It gives off only as much carbon dioxide when burned as it stores during its lifetime. In addition, wood fuel has low levels of sulfur, a chemical that contributes to acid rain.

Regularly coppiced plantations will actually absorb more carbon dioxide than mature trees – since carbon dioxide absorption slows once a tree has grown. Growing crops for fuel, particularly wood coppice, offers very

promising developments for the future. Short rotation arable coppicing, using fast-growing willows, is currently seen as an important source of fuel for electricity generation. The overall process involves several stages – growing over two or three years, cutting and converting to wood chip, storage and drying, and transport to a power plant for combustion. And the combustion process can be very efficient, given the development of advanced co-generation techniques.

Moreover, the security of energy supply will be significantly enhanced for many crop-growing countries. Energy crop production and use could reduce dependency on imported oil, although complete energy independence will remain a possible future event.

Crops – Residues

Crop residues and high yield-dedicated energy crops will not become cellulosic biomass supplies unless efficient, integrated biomass supply systems are developed. This means first of all, fully integrating crop production, harvesting and collection, storage, preprocessing, and transportation for each crop type and end use scenario.

Crop residues typically contain 40% of the nitrogen (N), 80% of the potassium (K), and 10% of the phosphorus (P) applied to the soil in the form of fertilizer. If these residues are subjected to direct combustion for energy, only a small percentage of the nutrients is left in the ash.

The valuable portion of sugar and starch crops (in terms of biofuel production) is the stalks and leaves, which are composed mainly of cellulose. The individual six-carbon sugar units in cellulose are linked together in extremely long chains by a stronger chemical bond than exists in starch. As with starch, cellulose must be broken down into sugar units before it can be used by yeast to make ethanol. However, the breaking of the cellulose bonds is much more complex and costly than the breaking of the starch bonds. Breaking the cellulose into individual sugar units is complicated by the presence of lignin, a complex compound surrounding cellulose, which is even more resistant than cellulose to enzymatic or acidic pretreatment. Because of the high cost of converting liquefied cellulose into fermentable sugars, agricultural residues (as well as other crops having a high percentage of cellulose) are not yet a practical feedstock source for small ethanol plants.

Crop residues (cobs, stems, leaves, in particular straw, and other plant matter) left in agricultural fields after harvest could potentially be used for solid biofuels production. Due to high energy content, straw is one of the best crop residues for solid biofuels. However, straw has several disadvantages – it has a higher ash content, which results in lower calorific value. In order to improve its bulk density, the straw is generally baled before transportation. Straw burning requires a specific technology. There are four basic types of straw burners: those that accept shredded, loose straw; burners that use densified straw products such as pellets, briquettes or cubes, and straw logs; small, square bale burners; and round bale burners. To be suitable for heat and electricity production, straw should not have a large content of moisture, preferably not more than 20% as the moisture reduces the boiler efficiency. Also, straw color as well as straw chemistry should be considered before burning as it indicates the quality of the straw.

Most crop residues are returned to the soil, and the humus resulting from their decomposition helps maintain soil nutrients, soil porosity, water infiltration, and storage, as well as reduce soil erosion.

Cross Draft Gasifier

In a cross draft gasifier, the air enters from one side of gasifier reactor and gas is taken out from other side. The cross draft gasifier is one of the simplest gasifier designs. It has a quick start-up time (5 to 10 minutes) relative to the start-up time of the downdraft and updraft units and reaches high temperatures which may require air- or water-cooled nozzles.

Unlike downdraft and updraft gasifiers, the ash bin, fire, and reduction zone in cross draft gasifiers are separated. The design characteristics limit the type of fuel for operation to low ash fuels such as wood, charcoal, and coke. The

load following ability of cross draft gasifier is quite good due to concentrated partial zones which operate at temperatures up to 2,000°C (3,630°F). The relatively higher temperature in cross draft gas producer has an obvious effect on gas composition such as high carbon monoxide, and low hydrogen and methane content when dry fuel such as charcoal is used. Cross draft gasifier operates well on dry air blast and dry fuel.

The cross draft gasifier requires low tar fuels like charcoal and like most gasifiers, fuel size is important to avoid bridging. Cross draft gasifiers are not used all that often because other gasifier designs offer more flexibility and better performance across fuel types.

The advantages of the system lie in the small scale at which it can be operated.

In developing countries, installations for shaft power less than 10 kW are used due to the simple gas cleaning section (cyclone and baghouse filter). A drawback is the minimal tar cracking performance, resulting in the need for high-quality charcoal.

See also: Gasification.

Crude Oil

Crude oil (also called petroleum or oil) occurs in formations beneath the surface of the Earth and is commonly refined into various types of fuels. As a fossil fuel, crude oil is formed when large quantities of dead organisms, mostly zooplankton and algae, are buried underneath sedimentary rock and subjected to heat and pressure.

The components of crude oil are separated using fractional distillation which is the separation of the crude oil into fractions differing in boiling point by means of distillation using a fractionating column.

Crude oil consists of naturally occurring hydrocarbon derivatives of various molecular weights and may contain miscellaneous organic compounds containing nitrogen, sulfur, and oxygen as well as trace metals.

Cryogenic Dehydration

The traditional method of cooling is the Joule-Thomson (JT) valve where the gas is expanded through the JT valve where the pressure drop cools the gas, to 5 to 10°C below the minimum specified for the export pipeline, and into a cold separator where the gas stream liquids and water condense out and are removed. The dry gas is then cycled back through a heat exchanger to pre-cool the incoming gas and to be warmed itself. The main disadvantage of this process is that the gas loses pressure, and may require recompression.

A more energy-efficient process is to use a turbo expander. The gas expands through a turbine and thus cools itself before it goes into the cold separator. The turbine can be connected to a compressor which recompresses the gas with only a small loss in overall pressure, or, if pressure recovery is not required, the turbine can drive a generator to provide electric power. These processes can only be applied if the gas pressure after expansion is sufficiently high for condensation of the heavier components to take place. If the gas arrives at low pressure, however, say less than 50 bar, an external mechanical refrigeration plant must be used to cool it to the specified temperature.

Flowing the gas through a bed of silica gel would remove hydrocarbons and water by adsorption. The bed can then be regenerated by passing hot dry gas over it. A bed of alumina would operate as a molecular sieve to remove only the water. These latter processes are easy to start up and to operate at high 'turn down' (changes in throughput), and so are useful for variable and 'on-off' operation.

See also: Gas Cleaning, Gas Processing, Gas Treating.

Cryogenic Equipment

This category of equipment contains turbo-expanders and the equipment associated with them. This category of equipment was not identified in the GRI study and so is a 'new' source of methane emissions. The total emissions

from turbo-expanders are small and contribute less than 3% of total methane emissions in a gas plant. The individual components contributing to emissions are valves, connectors, pressure-relief valves, compressor seals, and open-ended lines.

Cryogenic Expander Process

In the cryogenic expander process, a turboexpander is used to produce the necessary refrigeration and low temperatures, and high recovery of low-boiling components, such as ethane and propane, can be attained. Essentially, cryogenic processing consists of lowering the temperature of the gas stream to approximately -85°C (-120°F). There are several ways to perform this function, but the turbo expander process (in which external refrigerants are used to chill the gas stream) is the most effective. The quick drop in temperature that the expander is capable of producing condenses the hydrocarbons in the gas stream, but maintains methane in its gaseous form.

In the process, the gas stream is first dehydrated using a molecular sieve followed by cooling. The separated liquid containing most of the heavy fractions is then demethanized, and the cold gases are expanded through a turbine that produces the desired cooling for the process. The expander outlet is a two-phase stream that is fed to the top of the demethanizer column. This serves as a separator in which: (i) the liquid is used as the column reflux and the separator vapors combined with vapors stripped in the demethanizer are exchanged with the feed gas, and (ii) the heated gas, which is partially recompressed by the expander compressor, is further recompressed to the desired distribution pressure in a separate compressor. This process allows for the recovery of approximately 90 to 95% v/v of the ethane originally in the gas stream. In addition, the expansion turbine is able to convert some of the energy released when the gas stream is expanded into recompressing the gaseous methane effluent, thus saving energy costs associated with extracting ethane.

The cryogenic method is better at extraction of the lower-boiling liquids, such as ethane, than is the alternative absorption method.

See also: Gas Cleaning, Gas Processing, Gas Treating.

Cryogenic Separation

Cryogenic separation units operate by cooling the gas and condensing some, or all, of the constituents for the gas stream. Depending on the product purity required, separation may involve flashing or distillation. Cryogenic units offer the advantage of being able to separate a variety of products from a single feed stream. One specific example is the separation of low-boiling olefins from a hydrogen stream. Hydrogen recovery is in the range of 95%, with purity above 98% obtainable.

Cryosphere

The cryosphere is the collective term for the components of the Earth system that contain a substantial fraction of water in the frozen state (Table C-10). The cryosphere comprises several components: snow, river, and lake ice; sea ice; ice sheets, ice shelves, glaciers and ice caps; and frozen ground which exist, both on land and beneath the oceans, and the lifespan of each component is different. For example, river ice and lake ice are transient features that generally do not survive from winter to summer while sea ice advances and retreats with the seasons, and in Arctic region, the sea ice can survive to become multi-year ice lasting several years. Nevertheless, all components of the cryosphere are inherently sensitive to changes in air temperature and precipitation, and hence to a changing climate.

Table C-10 The main components of the Earth system.

System	Description
Atmosphere	The gaseous layer surrounding the earth and held to its surface by gravity; receives energy from solar radiation which warms the surface of the Earth and is re-emitted and conducted to the atmosphere; also absorbs water from the surface of the Earth via the process of evaporation and then acts to redistribute heat and moisture across the surface of the Earth. In addition, the atmosphere contains substances that are essential for life, including carbon, nitrogen, oxygen, and hydrogen.
Aquasphere	This consists of those parts of the earth system composed of water in its liquid, gaseous (vapor), and solid (ice) phases; includes: the oceans and seas, ice sheets, sea ice, glaciers, lakes, rivers, streams, atmospheric moisture, ice crystals, and areas of permafrost. The aquasphere includes both saltwater and freshwater systems as well as the moisture found in the soil (soil water) and within rocks (groundwater). In some classifications, the aquasphere is sub-divided into the fluid water systems (the hydrosphere) and the ice systems (the cryosphere).
Geosphere	The part of the Earth that is composed of rock and minerals; includes the solid crust, the molten mantle and the liquid and solid parts of the core of the Earth. In many places, the geosphere develops a layer of soil in which nutrients become available to living organisms, and which thus provides an important ecological habitat and the basis of many forms of life. The surface of the geosphere is subject to processes of erosion, weathering and transport, as well as to tectonic forces and volcanic activity, which result in the formation of landforms such as mountains, hills and plateaus.

Crystallization

Crystallization is the process of generating a solid crystalline material from a vapor, a melt, or a solution. In the first two cases, the crystallization is caused by cooling the medium to below the melting point of the crystals, after which the crystals separate from the vapor or the melt as solid crystals rather than as liquids and can be removed by settling, filtration, centrifuging, or cycloning.

When crystallizing from a saturated solution, the amount of solids that can remain dissolved in the liquid is reduced either by cooling – which is used where the solubility of the solids is a strong function of temperature – or by removal of liquid by evaporation – which is used when solubility is relatively insensitive to temperature.

The major advantage of crystallization over other separation methods is the ability of the process to precipitate essentially pure solids from a solution in a single stage. However, the process does not completely remove all of the solid material from the solution and further treatment of the residual saturated mother liquor is usually required.

The three requirements for solids crystallization from a solution are (i) the achievement of supersaturation, (ii) the nucleation of crystals, and (iii) crystal growth.

See also: Evaporation.

CTSL Process

The CTSL process (catalytic two-stage liquefaction process) was originally developed for the production of liquids from coal and is a further development of the H-Coal single-stage process and has been advocated as a means of producing biofuel from biomass.

In the process, the feedstock is slurried with a process-derived recycle solvent, preheated, mixed with hydrogen, and fed to the bottom of an ebullating bed reactor. This reactor contains a supported catalyst, generally nickel-molybdenum on alumina, which is fluidized by an internal recycle in the reactor. The reactor, therefore, has the characteristics of a uniform-temperature continuous-stirred tank reactor. The solvent acts as a hydrogen donor and solubilizes the coal by breaking down its structure to a substantial extent in the first reactor. This first reactor substantially dehydrogenates the solvent. Typically, operating conditions are on the order of 2,500 psi and a temperature of 400 to 410°C (750 to 770°F) but with biomass, the temperature may vary with the characteristics of the biomass feedstock.

The reactor products pass directly into the base of a second, ebullating-bed reactor stage, operating at the same pressure as the first stage but at a higher temperature (approximately 430 to 440°C, 805 to 825°F). This reactor also contains a supported catalyst, generally but not necessarily the same as that in the first reactor.

After separation and depressurization steps, the products from the second reactor enter an atmospheric distillation column, where distillate products boiling up to 400°C (750°F) are removed. The bottom stream from this column contains solvent, carbonaceous material, unreacted coal, and mineral matter. These solids are removed by one of several possible techniques and the solvent is recycled to the slurrying step. In some process variants, only part of the atmospheric column bottom stream is routed to the solids removal step, resulting in the recycle solvent containing mineral matter and any dispersed catalyst that may have been used.

See also: Liquefaction.

Cull Tree

A cull tree is a live tree, 5.0 in diameter at breast height (dbh) or larger that is cannot be used for sawing logs now or prospectively because of rot, roughness, or species.

A rough cull tree is a tree that does not meet regional standards that are required for sale because of excessive sound cull. This definition may also include noncommercial tree species.

A rotten cull tree is a tree that does not meet regional standards that are required for sale because of excessive unsound cull. This definition may also include noncommercial tree species.

See also: Wood.

Cultivated Summer Fallow

Summer fallow is land uncropped and plowed during the summer, in order to pulverize the soil and kill the weeds. It is also cropland in semi-arid regions that is purposely kept out of production during a cropping season mainly to conserve moisture for the next season. It is common for wheat producers in semi-arid regions to rotate half their cropland to summer fallow each year.

Cultivated summer fallow refers to cropland in sub-humid regions of the Western United States cultivated for a season or more to control weeds and accumulate moisture before small grains are planted. This practice is optional in some areas but necessary in the drier cropland areas of the West. Other types of fallow, such as cropland planted to soil improvement crops but not harvested, and cropland left idle all year, are not included in cultivated summer fallow.

See also: Crops, Crops-Residues.

Current Reserves

Current reserves are those resources that can profitably be extracted at current prices. Even though current reserve is usually given as a number, it usually fluctuates with prices. Sometimes, the current reserves are listed as the recoverable reserves (Table C-11).

Table C-11 Categorization of resources and reserves.

Resource	Undiscovered			
	Discovered	Nonrecoverable		
		Recoverable	Cumulative production	
			Reserves	Unproved
			(actual)	Probable
				Possible

Potential reserves represent the relationship between the market price for the resource and the amount of the resource that can be profitably extracted at that price. The higher the price, the greater the potential reserves.

See also: Reserves.

Cyclone Separation

A cyclone separator is a device for removing particulate matter from air or other gas streams and is a mechanically-aided collector that uses inertia to separate particulate matter from the gas stream as it spirals through the cyclone. Cyclone separators are generally used for collection of medium-sized and coarse particles.

Cyclones have a relatively simple construction and generally have no moving parts. Simple cyclones consist of (i) an inlet cylindrical section, (ii) a conical section, (iii) an outlet gas duct, (iv) an outlet dust tube, and (v) a collection hopper. A cyclone uses an induced draft fan to move the gas stream through the device. They are sized to provide the maximum inlet velocity possible for high separation without excessive turbulence. Multiple-cyclone separators consist of a number of small-diameter cyclones, operating in parallel and having a common gas inlet and outlet. Multiclones operate on the same principle as cyclones—creating a main downward vortex and an ascending inner vortex.

In general, a cyclone consists of an upper cylindrical part referred to as the barrel and a lower conical part referred to as cone. The air stream enters tangentially at the top of the barrel and travels downward into the cone forming an outer vortex. The increasing air velocity in the outer vortex results in a centrifugal force on the particles. Because of inertia, the particles resist the direction change as the gas turns, and they migrate toward the cylinder walls, separating them from the air stream. When the air reaches the bottom of the cone, an inner vortex is created reversing direction and exiting out the top as clean air while the particulates fall into the dust collection chamber attached to the bottom of the cyclone. The collection efficiency of a cyclone separator improves as the number of revolutions made by the gas and the gas velocity increase. However, the overall performance depends on the particle size distribution of the incoming gas stream.

A cyclone separator uses the centrifugal force created by a spinning gas stream to separate particles from a gas. The particulate-laden gas enters tangentially near the top of the device. The shape of the cyclone and the tangential entry force the gas flow into a downward spiral. Centrifugal force and inertia cause the particles to move outward, collide with the outer wall, and then slide downward to the bottom of the device. Near the bottom of the cyclone, the gas reverses its downward spiral and moves upward in a smaller inner spiral. The clean gas exits from the top through a vortex-finder tube, and the panicles exit from the bottom of the cyclone through a pipe sealed by a spring-loaded flapper valve or a rotary valve.

A cyclone separator can be constructed of any material, metal or ceramic that is capable of withstanding high temperatures, abrasive particles, or corrosive atmospheres. It is necessary that the interior surface of the separator is smooth so that the collected particles may slide easily down the wall to the hopper. The most common types of centrifugal, or inertial, collectors currently in use are single-cyclone separators and multiple-cyclone separators (multiclone).

See also: Centrifugal Separation, Gas Cleaning, Gas Processing, Gas Treating Particulate Matter Removal.

Cycloparaffin Hydrocarbons

Cycloparaffin hydrocarbons (also referred to as naphthenes) are hydrocarbon derivatives that contain a saturated ring system. These include derivatives of cyclopentane, cyclohexane, and decahydronaphthalene (decalin). In theory, the ring system may be built up of a varying number of carbon atoms, and among the synthesized hydrocarbons, there are individual constituents with rings of the three-, four-, five-, six-, seven-, and eight-carbon atoms (Table C-12). Thermodynamic studies show that naphthene rings with five and six carbon atoms are the most stable. The naphthenic acids contain chiefly cycle pentane as well as cyclohexane rings.

Table C-12 Types of cycloalkanes.

Alkane	Formula	Boiling point, °C	Melting point, °C	Liquid density*
Cyclopropane	C ₃ H ₆	−33	−128	
Cyclobutane	C ₄ H ₈	12.5	−91	0.720
Cyclopentane	C ₅ H ₁₀	49.2	−93.9	0.751
Cyclohexane	C ₆ H ₁₂	80.7	6.5	0.778
Cycloheptane	C ₇ H ₁₄	118.4	−12	0.811
Cyclooctane	C ₈ H ₁₆	149	14.6	0.834
Cyclononane	C ₉ H ₁₈	69	10-11	0.8534
Cyclododecane	C ₁₀ H ₂₀	201	9-10	0.871

Density of the liquid, g·cm^{−3} (at 20°C).

Cycloalkanes are similar to alkanes in terms of the general physical properties, but a cycloalkane has a higher boiling point, a higher melting point, and a higher density than the corresponding n-alkane.

The principal structural variation of cycloalkane derivatives is the number of rings present in the molecule. The mono- and bicyclic naphthene derivatives are generally the major types of cycloparaffins that occur in nature, with the boiling point or molecular weight increased by the presence of alkyl chains.

See also: Naphthenes.

Darcy's Law

For laminar single fluid flows in straight ducts, the flow resistance or pressure drop is proportional to the flow rate. The same relationship holds for flow in curved ducts when the flow velocity is small. This unique relationship between the flow velocity and the pressure drop can be generalized to the flow through porous media:

$$\frac{dp}{dx} - \rho g_x \propto -u$$

In this equation, u is the superficial fluid flow velocity (or discharge rate per unit cross-sectional area), p is the fluid pressure, x is the linear coordinate in the flow direction, ρ is the fluid density, and g_x is the gravity in the direction of flow. This limiting flow behavior has received great attention for centuries. It has been the basis for macroscopic modeling flow through packed beds; the proportionality constant can be determined if a flow geometry is defined.

A one-dimensional empirical model continuum, for saturated single fluid flow in porous media, was based on the proportionality, and Darcy's law can also be expressed as:

$$u = -\frac{k}{\mu} \left(\frac{\partial p}{\partial x} - \rho g_x \right)$$

In this equation, k is the permeability of the porous medium which is assumed to be constant in applications and μ is the dynamic viscosity of the fluid. Darcy's law has been generalized to be used for multi-dimensional single-phase and multiphase flows. Here, multiphase flows specifically mean immiscible multiphase flows. For miscible systems, one can effectively treat them as single-phase flows.

For single-phase flows, Darcy's law lacks both the flow diffusion effects and the inertial effects. Therefore, the utility of Darcy's law is restrictive and validation of the modeling results is often necessary. Remedies of these defects have been adjusted by addition of a diffusion term to the Darcy's law:

$$\nabla p - \rho \mathbf{g} = -\frac{\mu}{k} \mathbf{v} + \tilde{\mu} \nabla^2 \mathbf{v}$$

$\tilde{\mu}$ is an effective viscosity and $\mathbf{v}$ is the superficial fluid flow velocity. In general, the effective viscosity $\tilde{\mu}$ is proportional to the fluid viscosity μ and is affected by the type of porous media. For simplicity and convenience, the effective viscosity is usually taken to be identical to the fluid viscosity.

DEA

Diethanolamine, often abbreviated as DEA, is an organic compound with the formula $\text{HN}(\text{CH}_2\text{CH}_2\text{OH})_2$:

Diethanolamine

This colorless liquid is polyfunctional, being a secondary amine and a di-alcohol. Like other organic amines, diethanolamine acts as a weak base. DEA is soluble in water, even hygroscopic.

The alkanolamine derivatives and their aqueous solutions will absorb carbon dioxide and hydrogen sulfide at lower temperatures and release the acid gases at higher temperatures. This forms the basis for processes which separate carbon dioxide and hydrogen sulfide from gas streams.

Methyldiethanolamine is an alkanolamine used in gas treating and hydrogen sulfide enrichment units for selectively removing hydrogen sulfide from gas streams containing carbon dioxide. These units will, in most cases, permit 60 to 80% of the carbon dioxide to remain in the treated gas stream. Methyldiethanolamine is also used in natural gas plants for the bulk removal of carbon dioxide while producing a gas stream containing 0.25 grains hydrogen sulfide/100 ft³. Bulk carbon dioxide removal can be realized with methyldiethanolamine when the CO₂/H₂S ratio ranges from 100 to 1,000.

Similar compounds are monoethanolamine (MEA, H OCH₂CH₂NH₂), a primary amine, and diethanolamine (DEA, HOCH₂CH₂NHCH₂CH₂OH), a secondary amine, both of which are also used for in amine (olamine) gas treating units (Figure 4).

See also: Gas Cleaning, Gas Processing, Gas Treating.

Dehydration

Dehydration is the removal of water removal from gas streams, and there are several methods of dehydrating natural gas. The most common of these are liquid desiccant (glycol) dehydration, solid desiccant dehydration, and refrigeration (i.e., cooling the gas). However, the choice of dehydration method is usually between glycol and solid desiccants. Several other dehydration technologies (i.e., membranes, vortex tube, and supersonic processes) are less commonly used.

The first step in evaluating and/or designing a gas dehydration system is to determine the water content of the gas as a means of estimating water production with sour gas in the plant inlet separator. There are several methods available for determining the water content of sour gas streams at saturation, and one method is chart-based and provides good estimates of the equilibrium water vapor content of sour natural gas for a range of conditions including: hydrogen sulfide contents of 3 to 38 mole % with carbon dioxide contents of 3 to 43 mole %, pressures from 290 to 10,153 psi, and temperatures from 10 to 175°C (50 to 347°F). However, the error of this method can be as much as ±10%.

See also: Gas Cleaning, Gas Processing, Gas Treating.

Dehydration – Glycol Process

Among the different gas drying processes, absorption is the most common technique, where the water vapor in the gas stream becomes absorbed in a liquid solvent stream. Glycol derivatives are the most widely used absorption liquids as they approximate the properties that meet commercial application criteria. Several glycols have been found suitable for commercial application (Table D-1).

Table D-1 Examples of glycol derivatives used for dehydration of gas streams.

Glycol derivative	Description
Monoethylene glycol (MEG)	Has a high vapor equilibrium with gas. Tends to lose to gas phase in contactor. Suitable for use as hydrate inhibitor where it can be recovered from gas by separation at temperatures below 10°C (50°F).
Diethylene glycol (DEG)	Has a high vapor pressure that leads to high losses in the contactor. Low decomposition temperature requires low re-concentrator temperature (157 to 171°C; 315 to 340°F) and thus cannot get pure enough for most applications.
Triethylene glycol (TEG)	The most common glycol used. Reconcentrated at 171 to 204°C (340 to 400°F) for high purity. At contactor temperatures in excess of 49°C (120°F), there is a tendency to high vapor losses.
Tetraethylene glycol (TREG)	Less loss at high gas contact temperatures than TEG. Reconcentrated at 204 to 221°C (400 to 430°F).

Triethylene glycol is by far the most common liquid desiccant used in natural gas dehydration. It is regenerated more easily to a concentration of 98 to 99% in an atmospheric stripper because of its high boiling point and decomposition temperature. It also has an initial theoretical decomposition temperature of approximately 205°C (405°F), whereas that of diethylene glycol is approximately 165°C (328°F). Vaporization losses with triethylene glycol are lower than with monoethylene glycol or with diethylene glycol. Therefore, triethylene glycol can be regenerated easily to the high concentrations needed to meet pipeline water dew point specifications.

In the process, wet natural gas first typically enters an inlet separator to remove all liquid hydrocarbon derivatives from the gas stream. Then, the gas flows to an absorber (contactor) where it is contacted countercurrently and dried (water is removed) by the lean triethylene glycol.

Triethylene also absorbs volatile organic compounds (VOCs) that vaporize with the water in the reboiler. Dry natural gas exiting the absorber passes through a gas/glycol heat exchanger and then into the sales line. The wet or rich glycol exiting the absorber flows through a coil in the accumulator where it is preheated by hot lean glycol. After the glycol-glycol heat exchanger, the rich glycol enters the stripping column and flows down the packed bed section into the reboiler. Steam generated in the reboiler strips absorbs water and volatile organic compounds out of the glycol as it rises up the packed bed. The water vapor and desorbed natural gas are vented from the top of the stripper. The hot regenerated lean glycol flows out of the reboiler into the accumulator (surge tank) where it is cooled via cross exchange with returning rich glycol; it is pumped to a glycol/gas heat exchanger and back to the top of the absorber.

The process efficiency can be improved by additional equipment such as a cooling coil for the rich glycol stream that controls the water reflux rate at the top of the stripper and which ensures that the water vapor leaving the still does not carry over excess glycol. In addition, heat exchange between the cool rich glycol and the hot lean glycol is improved by using two or more shell and tube heat exchangers in series. The increased heat recovery reduces fuel consumption in the reboiler and protects the glycol circulation pump from being overheated; it also allows the flash tank and filter to operate at approximately 65°C (150°F). Higher flash temperatures will ensure maximum entrained gas to be removed from the rich triethylene glycol.

Dehydration – Solid Desiccant

Solid desiccant dehydration systems work on the principle of adsorption. Adsorption involves a form of adhesion between the surface of the solid desiccant and the water vapor in the gas. The water forms an extremely thin film that is held to the desiccant surface by forces of attraction, but there is no chemical reaction.

Solid desiccant dehydrators are typically more effective than glycol dehydrators, as they can dry a gas to less than 0.1 ppm v/v (0.05 lb/MMscf). However, in order to reduce the size of the solid desiccant dehydrator, a glycol dehydration unit is often used for bulk water removal. The glycol unit would reduce the water content to around 60 ppm v/v, which would help reduce the mass of solid desiccant necessary for final drying.

Using desiccant dehydrators as alternatives to glycol dehydrators can yield significant economic and environmental benefits, including reduced capital cost, reduced operation and maintenance cost, and minimal volatile organic compounds and hazardous air pollutants (BTEX – benzene, toluene, ethylbenzene, and xylenes).

The capacity of a desiccant for water is expressed normally in mass of water adsorbed per mass of desiccant. The dynamic moisture sorption capacity of a desiccant will depend on a number of factors, such as the relative humidity of the inlet gas, the gas flow rate, the temperature of the adsorption zone, the mesh size of the granule, and the length of service and degree of contamination of the desiccant and not the least on the desiccant itself. The moisture sorption capacity is not affected by variations in pressure, except where pressure may affect the other variables listed previously. There are three capacity terms used: (i) static equilibrium capacity, which is the water capacity of new, virgin desiccant as determined in an equilibrium cell with no fluid flow – corresponding to the adsorption isotherm, (ii) dynamic equilibrium capacity, which is the water capacity of desiccant where the fluid is flowing through the desiccant at a commercial rate, and (iii) the useful capacity, which is the design capacity that recognizes loss of desiccant capacity with time as determined by experience and economic consideration and the fact that all of the desiccant bed can never be fully utilized.

A variety of solid desiccants are available in the market for specific applications. Some are good only for dehydrating the gas, whereas others are capable of performing both dehydration and removal of heavy hydrocarbon components. The selection of proper desiccant for a given application is a complex problem. For solid desiccants

used in gas dehydration, the following properties are desirable: (i) a high adsorption capacity at equilibrium which lowers the required adsorbent volume, allowing for the use of smaller vessels with reduced capital expenditures and reduced heat input for regeneration, (ii) a high selectivity, which minimizes the undesirable removal of valuable components and reduces overall operating expenses, (iii) easy regeneration since the relatively low regeneration temperature minimizes overall energy requirements, (iv) low pressure drop, (v) good mechanical properties – such as high crush strength, low attrition, low dust formation, and high stability against aging – which lower the overall maintenance requirements by reducing the frequency of adsorbent change out and minimizing downtime-related losses in production, and (vi) materials that are noncorrosive, nontoxic, chemically inert, high bulk density and no significant volume changes upon adsorption and desorption of water.

The most common commercial desiccants used in dry bed dehydrators are silica gel, molecular sieves, and activated alumina. Silica gel (a generic name for a gel manufactured from sulfuric acid and sodium silicate) is a widely used desiccant, which can be used for gas and liquid dehydration and hydrocarbon recovery from natural gas. It is characterized by the following: (i) best suited for normal dehydration of natural gas, (ii) easily regenerated compared to molecular sieves, (iii) has high water capacity, where it can adsorb up to 45% of its own weight in water, (iv) capable of dew points to 60°C (140°F), and (v) costs less than molecular sieve. Silica gel used for natural gas drying should be water-stable – many types of silica gel will produce fines in contact with water.

Molecular sieves are crystalline alkali metal aluminosilicates comprising a three-dimensional interconnecting network of silica and alumina tetrahedral. The structure is an array of cavities connected by uniform pores with diameters ranging from approximately 3 to 10 Å, depending on the sieve type. A molecular sieve is the most versatile adsorbent because it can be manufactured for a specific pore size, depending on the application. It is (i) capable of dehydration to less than 0.1 ppm water content, (ii) the overwhelming choice for dehydration prior to cryogenic processes, which is especially true for liquefied gas, (iii) excellent for removal of hydrogen sulfide and carbon dioxide, as well as dehydration, high temperature dehydration, high-boiling hydrocarbon liquids, and highly selective removal, (iv) more expensive than silica gel, but offers greater dehydration, and (v) requires higher temperatures for regeneration, thus has a higher operating cost.

A molecular sieve dehydration system is also an alternative to the Drizo process. However, because of multiple high pressure and high temperature vessels, the installed cost of a molecular sieve system is two or three times more than an equivalent Drizo system.

There are several types of alumina available for use as a solid desiccant. Activated alumina is a manufactured or natural occurring form of aluminum oxide that is activated by heating. It is widely used for gas and liquid dehydration and will produce a dew point below -158°F if applied properly. Less heat is required to regenerate alumina than for molecular sieve, and the regeneration temperature is lower. However, molecular sieves give lower outlet water dew points.

It should be noted that no desiccant is perfect or best for all applications. In some applications, the desiccant choice is determined primarily by economics. Sometimes, the process conditions control the desiccant choice. If a unit is designed properly, it is quite rare that desiccants can be interchangeable. What is often possible is to replace within one class of adsorbents, i.e., molecular sieve of one supplier with molecular sieve from another.

During the adsorption step, the gas to be processed is sent on the adsorbent bed, which selectively retains the water. When the bed is saturated, hot gas is sent to regenerate the adsorbent. After regeneration and before the adsorption step, the bed must be cooled. This is achieved by passing through cold gas. After heating, the same gas can be used for regeneration. In these conditions, four beds are needed in practice in cyclic operation to dry the gas on a continuous basis: two beds operating simultaneously in adsorption or gas drying cycle, one bed in the cooling cycle, and one bed in the regeneration cycle.

Dehydrator Systems

Many gas dehydrator systems use triethylene glycol (TEG) to remove water from the natural gas stream in order to meet pipeline specifications. Often, the glycol circulation rate is set much higher than it needs to be in order to achieve this objective. Over-circulation leads to increased methane emissions. Operators can adjust this circulation rate at no additional cost and decrease methane emissions from the dehydrator system. Another way to decrease

methane emissions from triethylene glycol systems is to install flash tank separators. Flash tank separators capture approximately 90% of the methane entrained in the triethylene glycol systems, preventing the methane from being boiled off into the atmosphere when the triethylene glycol systems passes through the regenerator.

Desiccant dehydrators can be good alternatives to triethylene glycol systems under certain circumstances. Glycol dehydrators can be replaced altogether with desiccant dehydrators at a higher cost, nearly eliminating gas emissions and also saving both fuel gas used for the glycol reboiler (sometimes a gas heater) and pneumatic gas used for glycol-unit controllers. With no regenerator, desiccant dehydrators produce methane emissions only when they are being refilled with desiccant, and even then the volumes are far below those from triethylene glycol systems.

Delignification

The alkaline delignification of wood in the pulp industry is an example of a particularly complex system involving hundreds of reactions. This process is the key step in the production of cellulose via chemical pulping. The lignin material in the wood is partially decomposed and dissolved in the treating liquor, whereas cellulose fibers remain in a solid state; part of the hemicellulose constituents is also dissolved.

The chemical complexity and large variations in wood composition plays a major role in the efficiency of the process. The key concept is to identify the most important reactions and to merge certain classes of compounds, much in line with an understanding of crude oil refining and petrochemical. The apparatus used in the paper and pulp industry is somewhat different from that used in the crude oil industry or classical chemical industry.

The removal of lignin from the wood has traditionally taken place by the Kraft process. This usually involves digesting wood chips at high temperature and pressure, and in a solution of sodium hydroxide and sodium sulfide in water (white liquor). The white liquor chemically dissolves the lignin bonds that interconnect the cellulose fibers.

At this stage, the solid pulp is brown (brown stock) and the combined liquids (known as black liquor) contain the lignin fragments along with chemicals and by-products. The pulp is separated from the used cooking liquors by a series of washes. The lignin fragments are collected and burned to help power the factory. The rest of the process is designed to recycle the heat and cooking chemicals.

Some by-products of the Kraft process are turpentine and tall oil, which is a viscous material with a variety of industrial uses. The brown stock produced by the Kraft process contains approximately 5% w/w of residual lignin, and is further delignified by a series of bleaching stages. Bleaching removes additional lignin, making the paper brighter.

Oxygen delignification is a process that removes more lignin, and uses fewer chemicals. It involves treating the pulp with oxygen in a pressurized vessel at a high temperature in alkaline solution, which is followed by a washing stage. The amount of residual lignin can be decreased to approximately 1.5% with this method, thus limiting the degree of bleaching needed to make paper from the pulp.

The delignification process has traditionally focused on wood pulp for paper and fiberboard, but more recent efforts involved the use of biomass as a source of ethanol – an alternative to fossil fuels. This plant material must undergo delignification before it can be used for this purpose. Microbial systems are being engineered that combine the removal of lignin with the conversion of cellulose to ethanol.

Densification

Densification, such as briquetting or pelletization, is an important technique to densify biomass materials for increasing the particle size and bulk density. The reasons for biomass include (i) densified biomass is less expensive to transport, (ii) densified products are easier to store and handle, and (iii) densification enables certain biomass feedstocks to be gasified in a specific gasifier.

In its natural form, most biomass is difficult to utilize as a fuel because it is bulky, wet, and dispersed. Disadvantages of biomass as an energy source include inefficient transportation and large volumes required for storage. Solving these problems is where biomass densification gains extreme importance. Biomass densification is defined as compression

or compaction of biomass to remove inter- and intra-particle voids. Compression baling can reduce biomass volume to one-fifth of its loose bulk volume.

Densification of biomass is often necessary to combat the negative storage and handling characteristics of these low bulk density materials. A consistent, high-quality densified product is strongly desired, but not always delivered. Within the context of pelletizing and briquetting, binding agents are commonly added to comminuted biomass feedstocks to improve the quality of the resulting pellets or briquettes. Many feedstocks naturally possess such binding agents; however, they may not be abundant enough or available in a form or state to significantly contribute to product binding. Also, process parameters (pressure and temperature) and material variables (particle size and moisture content) can be adjusted to improve the quality of the final densified product.

Densification of ground biomass materials is still fully understood not a science, as much work is still required to fully understand how the chemical composition and physical properties, along with the process variables, impact product quality. Generating densification and compression data, along with physical and mechanical properties of a variety of biomass materials, will allow for a deeper understanding of the densification process. This in turn will result in the design of more efficient densification equipment, thus improving the feasibility of using biomass for chemical and energy production.

See: Briquetting, Pelletizing.

Deposition

Deposition is the reverse process of sublimation in which a solid is deposited from the gas phase without passing through the intermediate liquid phase.

Deposition

Gas → solid

Sublimation:

Solid → gas

In fact, there are several phase transformations that can occur when chemicals are released into the environment (Table D-2), complicating efforts to identify the original contaminant and even thwarting cleanup processes especially when the design of the cleanup process was based on knowledge of the original chemical.

Table D-2 Examples of phase transformations.

From	To	Process
Gas	Gas	N/A*
Gas	Liquid	Condensation
Gas	Solid	Deposition
Liquid	Gas	Evaporation or boiling
Liquid	Liquid	N/A*
Liquid	Solid	Freezing
Solid	Gas	Sublimation
Solid	Liquid	Melting
Solid	Solid	Transformation**

*May involve a chemical change depending upon the temperature and pressure

** For example, a change in crystal structure

Descending Bed Reactor

A descending bed system uses gravity downflow of packed solids contacted with upwardly flowing gases. The system is sometimes referred to as fixed bed reactor or moving bed reactor.

In such a reactor, combustion fumes, especially from power stations, can be cleaned prior to discharge into the atmosphere by rising through a reactor column in counter flow to the flow of a descending bed of reaction material. To ensure uniform distribution of fumes over the entire cross section of the descending bed, which is itself unobstructed by internal guides or deflectors, the conical lower section of the column consists of a series of overlapping slots between whose gaps the fumes enter – these slots may be individually adjusted for optimum fume distribution. A number of these reactors may be disposed side by side and at different vertical levels. In the reactor, the entire mass of solids descends uniformly, with no dead zones.

See also: Downflow Fixed Bed Reactor.

Desiccant Dehydrators

Desiccant dehydrators can be good alternatives to triethylene glycol systems under certain circumstances. A variety of solid desiccants are available in the market for specific applications. Some are good only for dehydrating the gas, whereas others are capable of performing both dehydration and removal of heavy hydrocarbon components. The selection of proper desiccant for a given application is a complex problem.

For solid desiccants used in gas dehydration, the following properties are desirable: (i) high adsorption capacity at equilibrium, which lowers the required adsorbent volume, allowing for the use of smaller vessels with reduced capital expenditures and reduced heat input for regeneration, (ii) high selectivity, which minimizes the undesirable removal of valuable components and reduces overall operating expenses, (iii) easy regeneration – the relatively low regeneration temperature minimizes overall energy requirements and operating expenses, (iv) good mechanical properties (such as high crush strength, low attrition, low dust formation, and high stability against aging), and (v) inexpensive, noncorrosive, nontoxic, chemically inert, high bulk density and no significant volume changes upon adsorption and desorption of water.

The most common commercial desiccants used in dry bed dehydrators are silica gel, molecular sieves, and activated alumina.

Silica gel (a generic name for a gel manufactured from sulfuric acid and sodium silicate) is a widely used desiccant, which can be used for gas and liquid dehydration and hydrocarbon recovery from natural gas. Silica gel used for natural gas drying should be stable to water. Most other silica gel types will produce fines in contact with water.

Molecular sieves are crystalline alkali metal aluminosilicates comprising a three-dimensional interconnecting network of silica and alumina tetrahedral. The structure is an array of cavities connected by uniform pores with diameters ranging from approximately 3 to 10 Å, depending on the sieve type. A molecular sieve is the most versatile adsorbent because it can be manufactured for a specific pore size, depending on the application.

There are several types of alumina available for use as a solid desiccant. Activated alumina is a manufactured or natural occurring form of aluminium oxide that is activated by heating. It is widely used for gas and liquid dehydration and will produce a dew point below -158°F. Less heat is required to regenerate alumina than for molecular sieve, and the regeneration temperature is lower.

No desiccant is perfect or best for all applications. In some applications, the desiccant choice is determined primarily by economics. Sometimes, the process conditions control the desiccant choice.

See also: Gas Cleaning, Gas Processing, Gas Treating.

Desorption

Desorption is the reverse of adsorption whereby adsorbed matter is removed from the adsorbent.

See also: Adsorption.

Deuterium

Deuterium (symbol D or ^2H , also known as heavy hydrogen) is one of two stable isotopes of hydrogen (Table D-3). The nucleus of deuterium (sometimes referred to as a deuteron) contains one proton and one neutron, whereas the far more common hydrogen isotope, protium, has no neutron in the nucleus.

Table D-3 The Isotopes of Hydrogen.

Isotope	Description
Protium	Ordinary hydrogen with one proton and one electron in the atom. When two atoms of protium are combined with one atom of oxygen, water is created.
Deuterium	Sometimes called "heavy hydrogen," a non-radioactive isotope that has a neutron in the atom, in addition to the proton and electron. Water made with this isotope is called "heavy water."
Tritium	A radioactive isotope of hydrogen that has two neutrons in addition to the proton and the electron. Water made with this isotope is called tritium oxide. Tritium is the only one of the three hydrogen isotopes that is radioactive.

Deuterium has a natural abundance in oceans of the Earth of approximately one atom in more than six thousand (6,420) of hydrogen. Thus deuterium accounts for approximately 0.0156% (or on a mass basis 0.0312%) of all the naturally occurring hydrogen in the oceans, while the most common isotope (hydrogen-1, sometimes referred to as protium) accounts for more than 99.98%. The abundance of deuterium changes slightly from one kind of natural water.

The physical properties of deuterium compounds can exhibit significant kinetic isotope effects and other physical and chemical property differences from the hydrogen analogs. Deuterium oxide (D_2O , heavy water), for example, is more viscous than common water (H_2O). Chemically, there are differences in bond energy and length for compounds of heavy hydrogen isotopes compared to normal hydrogen, which are larger than the isotopic differences in any other element. Bonds involving deuterium and tritium are somewhat stronger than the corresponding bonds in hydrogen, and these differences are enough to cause significant changes in biological reactions.

Deuterium can replace the normal hydrogen in water molecules to form heavy water (D_2O), which is approximately 10.6% denser than normal water (so that ice made from it sinks in ordinary water). Heavy water is slightly toxic in eukaryotic animals, with 25% substitution of the body water causing cell division problems and sterility, and 50% substitution causing death by cytotoxic syndrome (bone marrow failure and gastrointestinal lining failure). Prokaryotic organisms, however, can survive and grow in pure heavy water, though they develop slowly. Despite this toxicity, consumption of heavy water under normal circumstances does not pose a health threat to humans. Small doses of heavy water (a few grams in humans, containing an amount of deuterium comparable to that normally present in the body) are routinely used as harmless metabolic tracers in humans and animals.

In terms of quantum properties, the deuteron has spin +1 (triplet) and is thus a boson. The nuclear magnetic resonance (NMR) frequency of deuterium is significantly different from common light hydrogen. Infrared spectroscopy also easily differentiates many deuterated compounds, due to the large difference in infrared absorption frequency seen in the vibration of a chemical bond containing deuterium, versus light hydrogen. The two stable isotopes of hydrogen can also be distinguished by using mass spectrometry.

Deuterium and tritium are the main ingredients in most fusion reactions, and the fusion reaction deuterium and tritium into helium is only one of the possible reactions that could be the basis for the fusion power reactors of the future. The others are:

As an alternate energy source, nuclear offers several advantages over nuclear fission. One advantage is that the reserves of fusible isotopes are much larger than those of fissionable isotopes; in fact, they are essentially unlimited. Another advantage is that the products of fusion reactions are less radioactive than the products of fission reactions. Among the products of the fusion reactions listed above, only tritium and the neutrons are radioactive. The last advantage of fusion lies in its inherent safety. There would be little fusible material at any given time in the reactor, and the likelihood of a runaway reaction would thus be small. Furthermore, the reaction is so hard to achieve in the first place that small perturbations in reactor conditions would probably terminate it.

See also: Hydrogen, Nuclear Fission, Nuclear Fusion, Protium, Tritium.

Devolatilization

Devolatilization is the removal of material in the vapor phase by the action of heat either through boiling or thermal decomposition. The yield of volatile products is a function of operational conditions, including effects of reactor atmosphere gases, coal ranks, heating rates, ultimate devolatilization temperatures, pressure, residence time at ultimate temperatures, and catalysts.

An important factor of high-temperature devolatilization is the extent of secondary reactions. Higher volatile yields are obtained if the operational conditions allow secondary reactions to proceed so that coal can be degraded to tar, and tar to gaseous species. Another important factor is the reactor atmospheric gases. The two reacting gases are hydrogen and steam. A hydrogen atmosphere enhances the secondary reactions during the coal pyrolysis, and the effect of steam atmosphere is obtained because of physical processes that degrade and rupture fragments from coal and tar.

Minerals in the samples catalyze the devolatilization process by enhancing the secondary reactions by weakening chemical interactions with forming interactions between the volatile matter and mineral particles.

See also: Thermal Decomposition.

Dewatering

Dewatering is the removal of water from a carbonaceous material such as biomass by mechanical equipment such as a vibrating screen, filter, or centrifuge. Drying biomass fuel improves combustion efficiency, increases steam production, reduces air emissions, and improves boiler operation.

In a boiler or gasifier, moisture in the fuel must first be heated and evaporated, carrying with it a large quantity of heat up the stack. While a fuel dryer also consumes energy in heating and evaporating moisture, the drying is more efficient in equipment designed especially for this purpose. If heat for the dryer is recovered from the boiler flue gas or gasifier—or from other waste heat sources—efficiency is further increased. For wood chips with a moisture content on the order of 45% w/w, the maximum boiler efficiency with standard equipment is approximately 74%. If the same standard equipment is burning dry wood (on the order of 10% to 15% w/w moisture), the efficiency can be as high as approximately 80%. These efficiency improvements have corresponding steam production increases of 50% to 60%.

Thus, a biomass-fired boiler will perform better when fuel has an optimum dryness. If the fuel is too wet, it may be impossible to even keep the flame lit. With dry fuel, the flame burns hotter and more evenly, facilitating complete combustion. Also, a smaller quantity of ash is produced, reducing the cost of ash disposal. Boiler air emissions are reduced with a drier fuel, although emissions from the dryer must be considered. More complete combustion results in a lower quantity of fly ash up the boiler stack. In addition, excess air can be reduced significantly, which reduces

air velocities through the boiler and hence particulates in the flue gas. Drying biomass fuels reduces transportation costs. In addition, dry biofuels are less subject to microbiological degradation in storage.

Thus, overall efficiency can often be improved by dewatering wet feedstocks prior to thermal drying. On the downside, mechanical dewatering equipment itself can consume a large amount of energy and have high maintenance requirements, which must be weighed against the reduction in drying energy. Dewatering equipment includes drying beds, filters and screens, presses, and centrifuges. Depending on the material and the specific type of equipment, mechanical dewatering equipment may quickly reduce moisture content to as little as approximately 50%. More commonly, such a low moisture content cannot be achieved with mechanical dewatering equipment. Passive dewatering methods, such as using filter bags that are impervious to rain but allow moisture to seep out, can achieve moisture contents as low as 30% at low cost, but long periods of time – on the order of two to three months – may be required. Types of mechanical presses include belt filter presses, V-type presses, ring presses, screw presses, and drum presses. In a belt filter press, for example, the material is sandwiched between two porous belts, which are passed over and under rollers to squeeze moisture out. Belt presses are used in many industries, including wastewater treatment. A drum press consists of a perforated drum with a revolving press roll inside it that presses material against the perforated drum. This kind of press has been used with many materials, including hog fuel and bark. In a bowl centrifuge, the material enters a conical, spinning bowl in which solids accumulate on the perimeter. Belt filter presses typically have longer lives than centrifuges. Depending on the material, centrifuges can achieve lower moisture contents – on the order of 65% to 85% w/w moisture content compared to 76% to 88% w/w moisture content for belt presses when drying municipal sludge. The savings associated with achieving a lower moisture content can offset the higher first cost of a centrifuge.

The basic principles of dewatering are the same, irrespective of the type of the biomass, the size of the particles, or the machine that is being used. In every instance, a bed of particles is formed through which water and air flow under the action of a driving force. The biomass particles that comprise the bed invariably cover a wide range of sizes and composition. For example, the particles are rough and angular in shape, have an internal porosity which is full of water, often stick together, and will frequently contain a proportion of clay slime.

There are many types of dryers used in drying biomass, including direct- and indirect-fired rotary dryers, conveyor dryers, cascade dryers, and flash or pneumatic dryers. Selecting the appropriate dryer depends on many factors including the size and characteristics of the feedstock, capital cost, operation and maintenance requirements, environmental emissions, energy efficiency, waste heat sources available, available space, and potential fire hazard. Fuel dryers use superheated steam, hot air, or hot water as drying media. Air dryers derive heat from their own burners, from boiler flue gas, or from waste heat recovered from the exhaust of process heating in the facility. Water is often heated by waste heat recovery as well and can be transferred over longer distances from process equipment to the dryer than can air. Steam dryers use steam from the boiler. Dryers may be generally classified as either indirect- or direct-fired. In direct-fired dryers, flue gas or hot air is passed directly through the medium to be dried. In indirect-fired dryers, the heated medium is not passed directly through the material to be dried, but through tubes or other heat exchangers inside the dryer. Indirect-fired dryers may use flue gas or steam. Indirect dryers are well suited for drying fine and dusty materials.

Open-air drying is effective for some biomass materials, such as park trimmings or husks and stalks, can be allowed to dry naturally by storing in a covered, open area or by taking advantage of open-air solar drying. The final moisture content of air-dried materials usually varies from approximately 15% to 35%, depending on the size and characteristics of the material and ambient conditions. Open-air drying is slow and depends on weather conditions. The pile may need stirring or turning to facilitate drying. Open-air drying is generally not suitable for high water content feedstocks since they tend to decompose quickly.

In the perforated floor bin dryer, hot gases from the dryer's burner or flue gas recovered from boiler or gasifier are passed through the perforated floor into a large bin containing the feedstock. The depth of the feedstock in the dryer should not exceed 1 or 2 feet. The feedstock usually requires mixing after drying to achieve uniform moisture content.

In a rotary dryer, material is fed into a slowly rotating cylinder. Longitudinal flights inside the cylinder lift the feedstock and allow it to cascade down through the drying medium. Rotary dryers are in wide use and have a long, proven history in many industries and are the most commonly used dryer in drying hog fuel. On the other hand, high clay content paper sludges tend to ball up in a rotary dryer. Coarse bark has also been found to be problematic in rotary dryers.

Continuous-feed, direct-fired rotary dryers are the most common type of dryer for hog fuel, sawdust and bark, and many other materials. In general, the highest temperature possible without scorching the fuel results in greater dryer efficiency. An inlet temperature of around 800°F is optimum for hog fuels dried in a rotary drum direct dryer. Moisture fuels will require somewhat higher temperatures than drier fuels. But temperatures as low as 260°C (500°F) can be used with acceptable efficiencies in these dryers. Exhaust temperatures on the order of approximately 65°C (150°F) are typical. Compared to rotary steam-tube indirect-fired dryers (see below), direct-fired dryers have lower operation and maintenance costs and higher availability (i.e., less down time for maintenance). Lower-temperature dryers such as conveyor dryers and cascade dryers have several advantages over direct-fired rotary dryers. In comparison, direct-fired rotary dryers have greater emission of VOCs and particulates, lower opportunity to recover waste heat, and have greater fire hazard especially after the dryer and in shutdown. Exhaust from the dryer may need to be passed through a cyclone, baghouse filter, scrubber, or electrostatic precipitator to remove particulates.

Steam-tube dryers use steam from the power boiler to dry the fuel, passing the steam through tubes located inside the drum. Since this steam would otherwise be used to generate electricity, it does represent an energy cost. Indirect-fired dryers are less efficient than direct-fired dryers because they introduce an inefficiency associated with transferring heat from the steam tubes to the material.

In conveyor dryers, the feedstock is spread onto a moving perforated conveyor to dry the material in a continuous process. Fans blow the drying medium through the conveyor and feedstock, either upward or downward. If multiple conveyors are used, they can be in series or stacked (i.e., “multi-pass”). Conveyor dryers are very versatile and can handle a wide range of materials. They are not as commonly used in drying hog fuel but have several advantages, along with some disadvantages, compared to the more commonly used rotary dryers. Conveyor dryers are better suited to take advantage of waste heat recovery opportunities because they operate at lower temperatures than rotary dryers used in hog fuel drying.

Rotary dryers, for example, typically require inlet temperatures of at least 260°C (500°F) for drying hog fuel, but more optimally operate at approximately 425°C (800°F). In contrast, the inlet temperature of at least one commercially available vacuum conveyor dryer can be as low as approximately 5°C (10°F) above ambient, although more typically conveyor dryers operate at higher temperatures between 93 and 205°C (200 and 400°F). Because of their lower temperatures, conveyor dryers can even be used in conjunction with a boiler stack economizer to take maximum advantage of heat recovery from boiler flue gas. In this scenario, an economizer first recovers heat from the boiler flue gas. Then, exhaust from the economizer is used for fuel drying. Their lower temperature also means that there is a lower fire hazard. Emissions of volatile organic compounds (VOCs) from the dryer will also be lower.

Multi-pass conveyors, in which conveyors are arranged one above the other with material cascading down from upper conveyors to lower conveyors, save considerable space. Multi-pass dryers are common in many industries due to their small footprint and lower cost. The capital cost of conveyor dryers and rotary dryers is often comparable. However, a conveyor dryer may require less ancillary equipment for treatment of emissions, so for new installations, the overall cost may be less.

Cascade dryers have been widely used for biomass drying and can be considered of as a type of fluidized bed dryer. The material is introduced into a flowing stream of hot air in an enclosed chamber. It is carried upward by the air and then cascades back to the bottom to be lifted again. Material is drawn out through openings in the side of the chamber. Cascade dryers operate at intermediate temperatures between those of conveyor and rotary dryers. They have a smaller footprint than rotary and conveyor dryers. A disadvantage is that they are more prone to corrosion and erosion of dryer surfaces and so have higher maintenance costs.

In flash dryers (also referred to as pneumatic dryers), the feedstock is suspended in an upward flow of the drying medium, usually flue gas. Flash dryers are appropriate for drying a wide variety of materials. Flash dryers are generally cost effective only at larger scales. Electricity use by flash dryers is greater than that of other dryer types because high air flows are required to keep the material suspended. Flash dryers require a small particle size, and so shredders may be required, also increasing electrical use. Flash dryers have a small footprint.

Superheated steam dryers are similar to flash dryers, except the drying medium is steam from the boiler instead of flue gas. The steam is fed directly into the dryer, i.e., not through a heat exchanger as in steam-tube dryers. Its temperature stays above the saturation temperature, so the steam does not condense, transferring only sensible heat to the biomass. A larger quantity of steam at a lower temperature and pressure leaves the dryer than enters it. Superheated steam dryers can operate in a closed loop with low-pressure steam from the dryer being reheated and

injected back into the dryer. Since a larger quantity of steam exits the dryer, the excess must be bled off. If this excess steam is recovered for use in another process, a large fraction of the energy is recoverable. The material must be fed into the dryer by a pressure tight feeder, such as a rotary valve or plug screw feeder. Superheated steam dryers have no air emissions, no fire hazard, and a small footprint.

Diesel-Alcohol Emulsion

Because alcohols have limited solubility in diesel, a stable emulsion must be formed that will allow it to be injected before separation occurs. Numerous techniques have been evaluated to allow for the concurrent use of diesel and ethanol in compression ignition engines. Some of these techniques include alcohol fumigation, dual injection, alcohol-diesel fuel emulsions, and alcohol-diesel fuel blends. Among these approaches, only alcohol-diesel emulsions and blends are compatible with most commercial diesel engines. Since emulsions are difficult to achieve and tend to be unstable, blends—either as micro-emulsions or using co-solvents—are the most common approach as they are stable and can be used in engines with relatively no modifications.

Blends of ethanol with diesel fuel are often referred to as E-Diesel or eDiesel or oxygenated diesel – a term that is not particularly precise since diesel blends containing methyl ester (biodiesel) or any other additive that includes oxygen can be also described as oxygenated diesel. In e-diesel blends, standard diesel fuel (such as US No. 2) is typically blended with up to 15% v/v of ethanol using an additive package that helps maintain blend stability and other properties such as the cetane number and the lubricity. The additive package may comprise from 0.2% to 5.0% v/v of the blend.

The use of e-diesel can bring some reductions in diesel PM emissions, while contradictory reports exist on its effect on nitrogen oxides, carbon monoxide, and emissions of hydrocarbon derivatives. Perhaps the biggest advantage of e-diesel is its partially renewable character, especially if renewable ethanol is used as the blending stock.

Diesel Cycle

The diesel cycle is the thermodynamic cycle which approximates the pressure and volume of the combustion chamber of the diesel engine. It is characterized by having constant pressure during the combustion phase, in contrast to the Otto cycle which is an idealization of the process in a gasoline engine, which approximates the real behavior with constant volume during that phase.

The maximum thermal efficiency of a diesel cycle is dependent on the compression ratio and the cut-off ratio. It has the following formula:

$$\eta_{th} = 1 - \frac{1}{r^{\gamma-1}} \left(\frac{\alpha^\gamma - 1}{\gamma(\alpha - 1)} \right)$$

In this equation, η_{th} is thermal efficiency, α is the cut-off ratio, V_3/V_2 is the ratio between the end and start volume for the combustion phase, r is the compression ratio V_2/V_1 , and γ is ratio of specific heats (C_p/C_v). This formula only gives the ideal thermal efficiency. The actual thermal efficiency will be significantly lower due to heat and friction losses. The formula is more complex than the Otto cycle (petrol/gasoline engine) relation that has the following formula:

$$\eta_{otto,th} = 1 - \frac{1}{r^{\gamma-1}}$$

The additional complexity for the diesel formula comes around since the heat addition is at constant pressure and the heat rejection is at constant volume. The Otto cycle by comparison has both the heat addition and rejection at constant volume.

Comparing the two formulae, it can be seen that for a given compression ratio (r), the ideal Otto cycle will be more efficient. However, a diesel engine will be more efficient overall since it will have the ability to operate at higher compression ratios. If a petrol engine was to have the same compression ratio, then knocking (self-ignition) would occur and this would severely reduce the efficiency, whereas in a diesel engine, the self-ignition is the desired behavior. In addition, both of these cycles are only idealizations, and the actual behavior does not divide as clearly or sharply. And the ideal Otto cycle formula stated above does not include throttling losses, which do not apply to diesel engines.

Diesel engines are more efficient than Otto cycle engines overall, but only during partial load with fuel cut-off at part of the power stroke. Unless the vehicle is at full stroke injection, it is at partial rated power. Since diesel engines use the heating effect of compressing air to ignite fuel, it can inject as little or as much fuel as the situation demands. It is important to note that Otto cycle engines can be more efficient than Diesel cycle engines only when the engine is running at or near maximum power.

See also: Diesel Engine, Diesel Fuel.

Diesel Engine

Named for the German engineer Rudolph Diesel, this internal-combustion, compression-ignition engine works by heating fuels and causing them to ignite; can use either crude oil or bio-derived fuel.

A diesel engine uses the heat of compression to initiate ignition to burn the fuel, which is injected into the combustion chamber during the final stage of compression. This is in contrast to a gasoline engine which uses the Otto cycle, in which an air-fuel mixture is ignited by a spark plug.

Diesel engines are manufactured in two-stroke and four-stroke versions. They were originally used as a more efficient replacement for stationary steam engines. Since the 1910s, diesel-powered engines have been used in submarines and ships and use in locomotives, large trucks, and electric generating plants followed later. In the 1930s, diesel engines began to be used in a few automobiles.

See: Biodiesel, Diesel Cycle.

Diesel Fuel

Diesel fuel is a crude oil-derived distillate fuel oil that distills between 180 and 380°C (356 to 716°F). Several grades are available depending on the use – diesel oil for diesel compression ignition (cars, trucks, and marine engines) and light heating oil for industrial and commercial uses.

Diesel fuel oil is essentially the same as furnace fuel oil, but the proportion of cracked gas oil is usually less since the high aromatic content of the cracked gas oil reduces the cetane value of the diesel fuel.

Diesel fuel was originally straight-run product obtained from the distillation of crude oil. However, with the use of various cracking processes to produce diesel constituents, diesel fuels also may contain varying amounts of selected cracked distillates to increase the volume available for meeting the growing demand. Care is taken to select the cracked stocks in such a manner that specifications are met as simply as possible.

Under the broad definition of diesel fuel, many possible combinations of characteristics (such as volatility, ignition quality, viscosity, gravity, stability, and other properties) exist. To characterize diesel fuels and thereby establish a framework of definition and reference, various classifications are used in different countries. An example is the United States in which grades No. 1-D and 2-D are distillate fuels, the types most commonly used in high speed engines of the mobile type, in medium-speed stationary engines, and in railroad engines. Grade 4-D covers the class of more viscous distillates and, at times, blends of these distillates with residual fuel oils. No. 4-D fuels are applicable for use in low- and medium-speed engines employed in services involving sustained load and predominantly constant speed.

The cetane number is a measure of the tendency of a diesel fuel to knock in a diesel engine. The scale is based upon the ignition characteristics of two hydrocarbon derivatives, viz: n-hexadecane [cetane, $\text{CH}_3(\text{CH}_2)_{14}\text{CH}_3$] and 2,3,4,5,6,7,8-heptamethylnonane.

Cetane has a short delay period during ignition and is assigned a cetane number of 100; heptamethylnonane has a long delay period and has been assigned a cetane number of 15. Just as the octane number is meaningful for automobile fuels, the cetane number is a means of determining the ignition quality of diesel fuels and is equivalent to the percentage by volume of cetane in the blend with heptamethylnonane, which matches the ignition quality of the test fuel.

The manufacture of fuel oils at one time largely involved using what was left after removing desired products from crude oil. Now, fuel oil manufacture is a complex matter of selecting and blending various crude oil fractions to meet definite specifications, and the production of a homogeneous, stable fuel oil requires experience backed by laboratory control.

See: Biodiesel, Diesel Cycle, Diesel Fuel, Diesel Index.

Diesel Index

The diesel index is an approximation of the cetane number of diesel fuel calculated from the density and aniline point.

The presence of presence of paraffin hydrocarbon derivatives in diesel may be related by the aniline point which is the temperature at which aniline solubilizes the fuel in equal amount and a homogeneous mixture results. The greater the paraffin content, the higher will be the aniline point. Also, the API gravity of oil increases as the paraffin content rises. With the help of these properties, diesel index (DI) is given as:

$$\text{DI} = (\text{API} \times \text{Aniline point in } ^\circ\text{F})/100$$

The diesel index has been correlated with cetane number, and it has been found that the diesel index is directly proportional to cetane number. The cetane number is thus obtained from the diesel index. The value of diesel index should be at least 45.

See also: Cetane Index, Cetane Number.

Digester

A digester is an airtight vessel or enclosure in which bacteria decomposes biomass in water to produce biogas. There are three basic digester designs, and all of them can trap methane and reduce fecal coliform bacteria, but they differ in cost, climate suitability, and the concentration of manure solids they can digest.

A *covered lagoon digester*, as the name suggests, consists of a manure storage lagoon with a cover. The cover traps gas produced during decomposition of the manure. This type of digester is the least expensive of the three. Covering a manure storage lagoon is a simple form of digester technology suitable for liquid manure with less than 3% solids. For this type of digester, an impermeable floating cover of industrial fabric covers all or part of the lagoon. A concrete footing along the edge of the lagoon holds the cover in place with an airtight seal. Methane produced in the lagoon collects under the cover. A suction pipe extracts the gas for use. Covered lagoon digesters require large lagoon

volumes and a warm climate. Covered lagoons have low capital cost, but these systems are not suitable for locations in cooler climates or locations where a high water table exists.

A *complete mix digester* converts organic waste to biogas in a heated tank above or below ground. A mechanical or gas mixer keeps the solids in suspension. Complete mix digesters are expensive to construct and cost more than plug-flow digesters to operate and maintain. Complete mix digesters are suitable for larger manure volumes having solids concentration of 3% to 10%. The reactor is a circular steel or poured concrete container. During the digestion process, the manure slurry is continuously mixed to keep the solids in suspension. Biogas accumulates at the top of the digester. The biogas can be used as fuel for an engine-generator to produce electricity or as boiler fuel to produce steam. Using waste heat from the engine or boiler to warm the slurry in the digester reduces retention time to less than 20 days.

Plug-flow digesters are suitable for ruminant animal manure that has a solids concentration of 11% to 13%. A typical design for a plug-flow system includes a manure collection system, a mixing pit, and the digester itself. In the mixing pit, the addition of water adjusts the proportion of solids in the manure slurry to the optimal consistency. The digester is a long, rectangular container, usually built below-grade, with an airtight, expandable cover.

New material added to the tank at one end pushes older material to the opposite end. Coarse solids in ruminant manure form a viscous material as they are digested, limiting solids separation in the digester tank. As a result, the material flows through the tank in a *plug*. The average retention time (the time a manure plug remains in the digester) is 20 to 30 days. Anaerobic digestion of the manure slurry releases biogas as the material flows through the digester. A flexible, impermeable cover on the digester traps the gas. Pipes beneath the cover carry the biogas from the digester to an engine-generator set.

A plug-flow digester requires minimal maintenance. Waste heat from the engine-generator can be used to heat the digester. Inside the digester, suspended heating pipes allow hot water to circulate. The hot water heats the digester to keep the slurry at 25°C to 40°C (77°F to 104°F), a temperature range suitable for methane-producing bacteria. The hot water can come from recovered waste heat from an engine generator fueled with digester gas or from burning digester gas directly in a boiler.

Both batch and continuous digesters are commercially available. While batch systems may be suitable for some applications, they are labor intensive, and in developed countries are probably not appropriate to the steady production of gas on any significant scale. Mixing may be used in both batch and continuous digesters to enhance contact between the bacteria and substrate. It has, however, been argued that while mixing may increase conversion rates, it is not energy efficient. In two-stage systems, only the first stage is mixed. Multistage systems provide optimum conditions for the successive digestive steps, and further development may prove them to be economical for some biomass materials.

The final stage in the process is the disposal of the wastes. Essentially all the water entering the system will be present in the effluent. Direct recycle of the water after separation from the sludge cannot be practiced, as this will result in a buildup of toxic substances and eventual failure of the system. It is possible that some fraction of the water may be safely recycled, although data on this aspect have not been seen. Treatment of this large volume of water to remove the toxics is costly and is likely to be uneconomical other than in large-scale operations. It is normally assumed that the water, which is considered to have some nutritional value, will be used for irrigation. Due consideration will have to be given to the effect of trace metals and other toxic materials present, and the final disposition of the irrigated crops. The sludge, too, may be used for land application and as stated will generally have higher nitrogen content than the original material. On an absolute basis, there is, of course, less nitrogen due to losses as ammonia, and there may be additional losses on land application, as the nitrogen in the sludge is in a more volatile form. Nevertheless, the sludge resulting from the digestion of animal manure is considered to have improved fertilizer value over the original material.

Nearly all digester plants have ancillary processes to treat and manage all of the by-products. The gas stream is dried and sometimes sweetened before storage and use. The sludge liquor mixture has to be separated by one of a variety of ways, the most common of which is filtration. Excess water is also sometimes treated in sequencing batch reactors (SBRs) for discharge into sewers or for irrigation.

See: Aerobic Digestion, Anaerobic Digestion, Covered Lagoon Digester.

Digestion

Digestion is the biochemical conversion of organic material to biogas, a mixture of mainly methane and carbon dioxide. The biomass is converted by bacteria in an anaerobic environment. The energy of the biogas produced amounts 20 to 40% of the lower heating value of the feedstock.

Anaerobic digestion is a commercially proven technology and is widely used for treating wet organic wastes. Biogas can, for example, be used for firing engines. It can also be upgraded to natural gas quality and applied in grids. When used in an engine, the overall electrical conversion efficiency is on the order of 10 to 16%.

See: Aerobic Digestion, Anaerobic Digestion, Digester.

Dimethyl Ether

Due to air pollution and limited crude oil reserves, a clean alternative fuel (produced from a renewable resource) is desired. Dimethyl ether (DME), as a substitute of diesel oil and liquefied petroleum gas (LPG), is worth to be clean fuel due to its high cetane number and zero content of sulfur. Dimethyl ether can also be used as a hydrogen carrier for fuel cells, as aerosol propellants and as refrigerants. With the potential for biomass gasification technologies, synthesis of dimethyl ether from biomass as a raw material is attracting much attention. At present, the one-step synthesis of dimethyl ether from synthesis gas (STD, synthesis-gas-to dimethyl ether) has attracted attention. The main reactions included in the STD process can be depicted as follows:

Methanol Synthesis Reactions:

Methanol Dehydration Reaction:

Water Gas Shift Reaction:

With choosing equations (1) and (4) being independent reactions in methanol synthesis reactions and in combination with Equation (3) as dehydration reaction, the overall reaction for the synthesis gas to dimethyl ether process is:

These reactions form a synergistic system that allows higher syngas conversion per pass in the following manner: methanol produced by equations (1) and (2) is consumed in equation (3) to produce dimethyl ether and water; water is shifted by equation (4) to produce carbon dioxide and hydrogen which in turn are the reactants for the methanol synthesis reaction; therefore, the products of each reaction step are reactants of another step. Due to a synergy effect, thermodynamic restrictions for single pass conversion of syngas was destroyed in the synthesis gas to dimethyl ether process.

The most popular catalyst used in the dimethyl ether synthesis is usually prepared by the mechanical mixing of two components, solid acid as dehydration and Cu-based catalyst for methanol synthesis. In contrast, less effort has been spent on the agent used for dehydration of methanol.

Dehydration in the bi-functional catalyst plays an important role in dimethyl ether synthesis. Solid acid dehydrators include aluminum oxides and zeolite. Because the optional temperature for methanol synthesis usually lies

below the temperature for dehydration in the presence of γ -Al₂O₃, the Cu-based catalyst is easy to deactivate, which brings on low overall activity for the bi-functional catalyst. For this reason, extensive research has been made on using zeolite as the dehydration. Because the Si-Al ratio of zeolite will impact the number of acid sites as well as the acid strength of the catalysts, this can lead to a strong influence on the selectivity of dimethyl ether.

Dimethyl ether can be produced from a variety of biomass sources and is considered a promising substitute for diesel and liquefied petroleum gas (LPG) as it can be stored in cylinders at low pressures. However, for vehicle use, dimethyl ether attacks sealing materials (using metal to metal, graphite, Teflon). It can be used in place of diesel; its energy density is approximately 80% that of diesel, the cetane number 55-60 (46-57.8 for diesel) and zero sulfur and aromatics (environmentally friendly). In compressions ignition engines, there have been reports of lower noise levels and emissions (NO_x reductions may be further improved by end of pipe abatement).

See: Fischer Tropsch, Gasification.

Direct Biofuels

Direct biofuels are biofuels that can be used in existing unmodified diesel engines. Because engine technology changes all the time, exactly what a direct biofuel is can be hard to define; a fuel that works without problem in one unmodified engine may not work in another engine. In general, newer engines are more sensitive to fuel than older engines, but new engines are also likely to be designed with some amount of biofuel in mind.

Straight vegetable oil can be used in some (older) diesel engines. Only in the warmest climates can it be used without engine modifications, so it is of limited use in colder climates. Most commonly, it is turned into biodiesel. No engine manufacturer explicitly allows any use of vegetable oil in their engines.

Biodiesel can be a direct biofuel. In some countries, manufacturers cover many of their diesel engines under warranty for 100% biodiesel use. Many people have run thousands of miles on biodiesel without problem, and many studies have been made on 100% biodiesel. In many European countries, 100% biodiesel is widely used and is available at thousands of gas stations.

Ethanol is the most common biofuel, and over the years, many engines have been designed to run on it. Many of these could not run on regular gasoline. It is open to debate if ethanol is a direct replacement in these engines though – they cannot run on anything else. In the late 1990s, engines started appearing that by design can use either fuel. Ethanol is a direct replacement in these engines, but it is debatable if these engines are unmodified, or factory modified for ethanol.

Butanol is often claimed as a direct replacement for gasoline. It is not in widespread production at this time, and while it appears that butanol has sufficiently similar characteristics with gasoline such that it should work without any problems in any gasoline engine.

See: Biofuels, Ethanol, Methanol, Propanol And Butanol.

Direct Combustion

Direct combustion involves burning the energy crop and then using the resulting hot combustion gases to raise steam. The steam is, in turn, used to drive a steam turbine which drives a generator to produce electricity. The conversion efficiency from energy crop to energy is fairly low, especially for small systems, but this is balanced by the relatively low capital cost of direct combustion systems and the fact that the technology is tried and tested. Furthermore, using the waste heat produces much better efficiencies and economics.

Combustion facilities can burn many types of biomass fuel, including wood, agricultural residues, wood pulping liquor, municipal solid waste (MSW), and refuse-derived fuel. Combustion technologies convert biomass fuels into several forms of useful energy for commercial or industrial uses: hot air, hot water, steam, and electricity.

A furnace is the simplest combustion technology. In a furnace, biomass fuel burns in a combustion chamber, converting biomass into heat energy. As the biomass burns, hot gases are released and these gasses contain approximately 85% of the potential energy of the fuel. Commercial and industrial facilities use furnaces for heat either directly or indirectly through a heat exchanger in the form of hot air or water.

A biomass-fired boiler is a more adaptable direct combustion technology because a boiler transfers the heat of combustion into steam. Steam can be used for electricity, mechanical energy, or heat. Biomass boilers supply energy at low cost for many industrial and commercial uses.

Pile burners consist of cells, each having an upper and a lower combustion chamber. Biomass fuel burns on a grate in the lower chamber, releasing volatile gases. The gases burn in the upper (secondary) combustion chamber, and pile burners must be shut down periodically to remove ash.

Although capable of handling high-moisture fuels and fuels mixed with dirt, pile burners have become obsolete with the development of more efficient combustion designs with automated ash removal systems.

In a stationary or traveling grate combustor, an automatic feeder distributes the fuel onto a grate, where the fuel burns. Combustion air enters from below the grate. In the stationary grate design, ashes fall into a pit for collection. In contrast, a traveling grate system has a moving grate that drops the ash into a hopper.

Fluidized-bed combustors burn biomass fuel in a hot bed of granular material, such as sand. Injection of air into the bed creates turbulence resembling a boiling liquid. The turbulence distributes and suspends the fuel. This design increases heat transfer and allows for operating temperatures below 972°C (1,700°F), reducing nitrogen oxide (NO_x) emissions. Fluidized-bed combustors can handle high-ash fuels and agricultural biomass residue.

Conventional combustion equipment is not designed for burning agricultural residues. Straw and grass contain alkali (potassium and sodium) compounds, which are also present in all annual crops and crop residues and in the annual growth of trees and plants. During combustion, alkali combines with silica, which is also present in agricultural residues. This reaction causes slagging and fouling problems in conventional combustion equipment designed for burning wood at higher temperatures.

Volatile alkali lowers the fusion temperature of ash. In conventional combustion equipment having furnace gas exit temperatures above 790°C (1,450°F), combustion of agricultural residue causes slagging and deposits on heat transfer surfaces. Specially designed boilers with lower furnace exit temperatures could reduce slagging and fouling from combustion of these fuels. Low-temperature gasification may be another method of using these fuels for efficient energy production while avoiding the slagging and fouling problems encountered in direct combustion.

Combustion facilities that produce electricity from steam-driven turbine-generators have a conversion efficiency on the order of 17 to 25%. Using a boiler to produce both heat and electricity (cogeneration) improves overall system efficiency to as much as 85%. That is, cogeneration converts 85% of the fuel's potential energy into useful energy in two forms: electricity and steam heat.

Two cogeneration arrangements, or cycles, are possible for combining electric power generation with industrial steam production. Steam can be used in an industrial process first and then routed through a turbine to generate electricity. This arrangement is called a bottoming cycle. In the alternate arrangement, steam from the boiler passes first through a turbine to produce electric power. The steam exhaust from the turbine is then used for industrial processes or for space and water heating. This arrangement is called a topping cycle.

The direct-fired gas turbine is another combustion technology for converting biomass to electricity. In this technology, fuel pretreatment reduces biomass to a particle size of less than 2 millimeters and a moisture content of less than 25%. Then, the fuel is burned with compressed air. Cleanup of the combustion gas reduces particulate matter before the gas expands through the turbine stage. The turbine drives a generator to produce electricity.

Co-firing biomass as a secondary fuel in a coal-burning power plant using high-sulfur coal could help reduce sulfur dioxide and nitrogen oxide emissions. Also, co-firing decreases net carbon dioxide emissions from the power plant (if the biomass fuel comes from a sustainable source). Co-firing may require wood fuel preparation or boiler modifications to maintain boiler efficiency.

See: Combustion.

Direct-Fired Biomass

The technologies for the conversion of biomass for electricity production are direct combustion, gasification, and pyrolysis.

Direct combustion (Figure 1) involves the oxidation of biomass with excess air, producing hot flue gases which in turn produce steam in the heat exchange sections of boilers. The steam is used to generate electricity in a Rankine

cycle; usually, only electricity is produced in a condensing steam cycle, while electricity and steam are cogenerated in an extracting steam cycle. Currently, biomass-fired steam cycle plants typically use single-pass steam turbines.

However, in the past decade, efficiencies and more complex design features, characteristic previously of only large-scale steam turbine generators (>200 MW), have been transferred to smaller capacity units. Current biomass designs include reheat and regenerative steam cycles as well as supercritical steam turbines. The two common boiler configurations used for steam generation with biomass are stationary- and traveling-grate combustors (stokers) and atmospheric fluid-bed combustors.

See: Combustion.

Dispersion

The dispersion of chemicals into the environment can occur in three ways: (i) dispersion during combustion processes, such as fuel conversion or waste incineration: chemicals released include polycyclic aromatic hydrocarbon derivatives, dioxin derivatives, and furan derivatives, (ii) dispersion after the unintentional release of chemicals following accidents or by slow leakage such as the release of polychlorinated biphenyl derivatives from electrical installations, and (iii) the intentional dispersion of chemicals as, for example, during the use of pesticides and other agricultural chemicals.

Thus, the disposal of a chemical into a water course and subsequent transportation of the chemical are referred to as dispersion. This is often a result of water surface turbulence, but also may result from the application of chemical agents (dispersants). The dispersed chemicals may remain in the water column or coalesce with other chemicals (the same chemical or different chemicals) and gain enough energy to be adsorbed by minerals, soil, or sediment.

In the context of the geosphere, dispersion is a process that occurs in soil that is particularly vulnerable to erosion by water. In a soil layer where clay minerals are saturated with sodium ions (*sodic soil*), the soil can break down very easily into fine particles and wash away. This can lead to a variety of soil and water quality problems, including: (i) large losses of soil losses by gully erosion and tunnel erosion, (ii) structural degradation of the soil, clogging, and sealing where dispersed particles settle, and (iii) turbidity in water due to suspended soil particles which also cause transportation of nutrients from the land. Dispersive soil is more common in older landscapes where leaching and illuviation processes have had more time to show an effect.

Briefly, gully erosion involves creation of a gully created by running water, eroding sharply into soil and typically occurs on a hillside. On the other hand, tunnel erosion occurs in some soils where channels and tunnels develop beneath the surface. It is insidious as it is not readily noticeable (apart from small sediment fans at the tunnel discharge point) until the surface itself is undermined. Illuvium is material displaced across a soil profile, from one layer to another one, by the action of rainwater.

The dispersion of chemicals released into the environment has been the focus of much attention because of the realization that the dispersion behavior of chemicals can be markedly different when different chemicals are considered. Accidents that involve chemicals give rise to a new class of problems in dispersion prediction for the following reasons: (i) the material is, in almost all cases, stored as a solid but may also emit a gas after a spill and exposure to the air, (ii) the modes of release can vary widely and geometry of the source can take many forms and the initial momentum of the spill may be significant, (iii) in some cases, a chemical transformation also takes place as a result of reaction with water vapor in the ambient atmosphere.

Emissions of many chemicals of concern occur into the air initially, from where they are dispersed into other media. Many chemicals emitted into the air, for instance from combustion processes, tend to become associated with particulate matter. Removal from the air occurs through a range of complex processes involving photodegradation, and particle sedimentation and/or precipitation (known respectively as *dry deposition* and *wet deposition*). Chemicals may undergo several cycles of physical and/or chemical transformation which can also make chemicals more accessible to photochemical or biodegradation.

In addition, the physical properties of the chemical may result in one or more interactions with the surrounding ecosystem, especially if the chemical is reactive and has the potential to react quickly with the air, water, or soil. This reactivity will influence the dispersability of the chemical, and, moreover, if the release occurs over a short time scale, compared to the steady-state releases characteristic of many chemical release problems, this can give rise to the

complication of predicting dispersion for time varying releases. There is also the uncertainty of individual predictions resulting from variability related to the behavior of a mixture. Also, the dispersing chemical, which is typically denser than air, may form a low-level cloud that is sensitive to the effects of either natural or man-made obstructions in the surrounding topography.

Wind transport (Aeolian transport – relocation by wind) can also occur and is particularly relevant when dust from solids (even coke dust which contains deposited chemicals) and catalyst dust are also considered. Dust becomes airborne when winds traversing arid land with little vegetation cover pick up small particles such as catalyst dust, coke dust, and other debris and send them skyward after which the movement of pollutants in the atmosphere is caused by transport, dispersion, and deposition. Dispersion results from local turbulence, that is, motions that last less than the time used to average the transport. Deposition processes, including precipitation, scavenging, and sedimentation, cause downward movement of pollutants in the atmosphere, which ultimately move the pollutants back to the ground surface but not necessary in the locals from which the pollutants originated.

Dissolution

Dissolution is the process whereby chemicals (such as gases, liquids, or solids) dissolve into a liquid (such as water or another solvent) by which these chemicals in the original state (gas, liquid, or solid) become a solute (dissolved component), forming a solution of the gas, liquid, or solid in the original solvent. On the other hand, solid solutions are the result of dissolution of one solid into another (such as metal alloys) and occur where the formation is governed and described by the relevant phase diagram. In the case of a crystalline solid dissolving in a liquid, the crystalline structure must be disintegrated such that the separate atoms, ions, or molecules are released. For liquids and gases, the molecules must be able to form non-covalent intermolecular interactions with those of the solvent for a solution to form. Dissolution is of fundamental importance in all chemical processes, especially the solubility of chemicals in water which can be enhanced by the occurrence of acid rain.

Generally, many chemicals (especially the inorganic chemicals) are polar and are usually soluble in water but insoluble in organic solvents (such as diethyl ether, dichloromethane, chloroform, and hexane). The solubility (dissolution) characteristics of chemical species in water is complex and very much dependent upon the structure and properties of the chemical(s). The chemical may be a gas, a liquid, or a solid (the solute) that dissolves in water – the solubility depends on the physical and chemical properties of the chemicals as well as on temperature, pressure, and the pH (acidity or alkalinity of the water).

Furthermore, the extent of solubility of the chemical can range from infinitely soluble (without limit) to poorly soluble (such as some lead salts) – the term *insoluble* is often applied to poorly or very poorly soluble compounds, and (in the world of chemistry) a common threshold to describe a chemical as insoluble is a solubility less than 0.1 g per 100 mL of water. However, solubility of a chemical in water should not be confused with the ability of water to dissolve the chemical because apparent solubility of the chemical might also occur because of a chemical reaction (*reactive solubility*).

Solubility of a chemical in water applies not only to environmental chemistry but to areas of chemistry, such as (alphabetically): biochemistry, geochemistry, chemistry, and physical chemistry. In all cases, the solubility of the chemical depends on the physical conditions (temperature, pressure, and concentration of the chemical) and the enthalpy and entropy relating to the water and the chemicals concerned. Water is, by far, the most common solvent in chemistry and is a solvent for a wide range of chemicals, especially those chemicals that readily form ions. This is a crucial factor in which acidity and alkalinity play a role as in much of the area known as environmental chemistry.

In addition, the term *dissolved chemicals* (or *total dissolved solids*) is used as a broad classification for chemicals of varied origin and composition within aquatic systems (the aquasphere). The source of the dissolved chemical in freshwater systems and in marine systems depends on the body of water. When water comes into contact with highly ionizable chemicals, these chemicals can drain into rivers and lakes as a dissolved chemical. Whatever the source of the dissolved chemical, it is also extremely important in the transport of metals in aquatic systems – certain metals can form extremely strong metallic complexes with a dissolved solute which enhances the solubility of the metal in aqueous systems while also reducing the bioavailability of the metal.

In terms of chemicals that do not occur naturally in the environment, knowledge of the structure and properties can be used to examine relationships between the solubility properties of the chemical and its structure, and vice versa. In fact, structure dictates function which means that by knowing the structure of a chemical, it may be (but not always) possible to predict the properties of the chemical such as its solubility, acidity or basicity, stability, and reactivity. In the context of environmental distribution of a chemical, predicting the solubility of a molecule is a useful component of knowledge.

Dissolved chemicals are generally associated with the various characteristics of drinking water (such as taste, smell, color, and odor), and the quality of drinking water, as perceived by the senses, largely determines the acceptability of water. For health-related contaminants – a contaminant that is unsafe for one species of flora or fauna should be considered unsafe for all, until proven otherwise – the general characteristics (taste, smell, and odor) are subject to social, economic, and cultural considerations.

On the other hand, the presence of (non-dissolved) suspended solids in water gives rise to turbidity. Suspended solids may consist of clay, silt, airborne particulates, colloidal organic particles, plankton, and other microscopic organisms. The presence of particulate matter in water may not only be offensive to the general senses but can also, in a more serious aspect, protect bacteria and viruses from the action of disinfectants. In addition, the adsorptive capacity of some suspended particulates can lead to entrapment of undesirable inorganic compounds and organic compounds present in the water and in this way, turbidity can bear an indirect relationship to the health aspects of water quality.

Distillation

Distillation has remained a major process for the separation of mixtures for several centuries, in particular for the separation of mixtures containing volatile organic compounds. The process consists of heating a liquid to its boiling point, separating the vapors from the liquid, and then condensing the vapors to form a new liquid phase, and the condensate contains a higher concentration of the more volatile component than did the original feedstock. If the difference in boiling point between the components of the feed is large, it may be possible to achieve the desired purification in a simple apparatus. On the other hand, if the difference is only a few degrees, a satisfactory separation may require a complex apparatus and a lot of energy. Fortunately, many of the distillations encountered in biomass conversion to liquids and also in waste disposal involve differences in boiling point between the components in the feed. Thus, the components in the feed can usually be separated in a single-stage batch still. The range of liquids that can be distilled runs from liquefied gases at low temperatures and/or high pressure up to high boiling liquids under vacuum just below their thermal decomposition temperature.

Generally, the maximum permissible temperature (in the vaporizing furnace or heater) to which the feedstock can be subjected is 350°C (660°F). The rate of thermal decomposition increases markedly above this temperature, although higher temperatures (up to approximately 395°C, 745°F) are part of the specifications for some distillation units – serious cracking does not occur at these higher temperatures but is subject to the properties of the crude oil feedstock and the residence time of the feedstock in the hot zone. If unplanned cracking occurs within a distillation unit, coke deposition can occur in the heater pipes or in the tower itself, resulting in failure of the distillation unit. In the modern sense, distillation was the first method by which crude oil-based fuels were refined.

Batch Distillation

The batch distillation process consists of placing a quantity of feedstock in a vessel, heating it to generate vapors, and then condensing the vapors in a separate vessel or condenser by cooling them to below their condensing temperature. The condensed vapors are the distillate, or overhead, and the residue left in the boiler when the distillation is finished is called the still bottoms or residue.

In the simplest form, a batch still is the combination of a boiler and condenser. However, it can also have large numbers of vapor-liquid contacting stages inserted between the boiler and the condenser in the form of a distillation column or tower. This greatly increases the composition difference between the distillate and the contents of the boiler and makes the separation much sharper. However, when this type of still is started, it must be run at total

reflux for several hours before starting to collect product which allows time for the concentration gradient to be established in the column.

Continuous Distillation

Continuous distillation is the process in which the feedstock is continuously fed to the distillation apparatus by either gravity flow or by means of a suitable pump along with flow rate control to provide the continuous feed. The continuous distillation process can vary in complexity from a simple one-stage equilibrium flash separation to a compound column having many enriching and stripping stages in a single apparatus. The equilibrium flash is generally used where the separation is achieved because of a substantial difference in volatility between the components to be separated. It is also useful when a small amount of relatively volatile material must be removed from a large amount of higher boiling material.

Multistage distillation is usually used to separate and recover materials which have relatively close boiling points, that is, less than 20°F apart. Typical continuous multistage separations can use enriching columns, stripping columns, or compound columns. Enriching columns are used to recover high purity lower boiling products from higher boiling point mixtures. In contrast, stripping columns are used to remove lighter materials from heavier products that are desired in high purity.

Distillation at Atmospheric Pressure

Distillation columns are the most commonly used separation units in a refinery. Operation is based on the difference in boiling temperatures of the liquid mixture components, and on recycling counter-current gas-liquid flow. The temperature distribution up the column results in different mixture compositions at different heights. While multi-component inter-phase mass transfer is a common phenomenon for all column types, the flow regimes are different depending on the internal elements used. The two main types are a tray column and a packed column, the latter equipped with either random or structured packing. Different types of distillation columns are used for different processes, depending on the desired liquid holdup, capacity (flow rates), and pressure drop, but each column is a complex unit, combining many structural elements.

Heat exchangers are also used to preheat the feedstock before it enters the furnace. These exchangers are bundles of tubes arranged within a shell so that a stream passes through the tubes in the opposite direction of a stream passing through the shell. Thus, cold crude oil, by passing through a series of heat exchangers where hot products from the distillation tower are cooled, before entering the furnace and saving of heat in this manner, may be a major factor in the economical operation of refineries.

Steam reboilers may take the form of a steam coil in the bottom of the fractional distillation tower or in a separate vessel. In the latter case, the bottom product from the tower enters the reboiler where a part is vaporized by heat from the steam coil. The hot vapor is directed back to the bottom of the tower and provides part of the heat needed to operate the tower. The non-volatile product leaves the reboiler and passes through a heat exchanger, where its heat is transferred to the feed to the tower. Steam may also be injected into a fractional distillation tower not only to provide heat but also to induce boiling to take place at lower temperatures. Reboilers generally increase the efficiency of fractionation, but a satisfactory degree of separation can usually be achieved more conveniently by the use of a *stripping* section. The *stripping operation* occurs in that part of the tower below the point at which the feed is introduced. The more volatile components are stripped from the descending liquid. Above the feed point (the rectifying section), the concentration of the less volatile component in the vapor is reduced.

Distillation at Reduced Pressure

The boiling range of the highest boiling fraction that can be produced at atmospheric pressure is limited by the temperature at which the residue starts to decompose or *crack*. If the atmospheric residuum is required for the manufacture of lubricating oils, further fractionation without cracking may be desirable, and this may be achieved by distillation under vacuum. The residua produced by distillation under reduced pressure have properties markedly different from the residua produced by distillation at atmospheric pressure.

In the vacuum tower, the feedstock is charged through a heater into the vacuum column in the same manner as whole crude is charged to an atmospheric distillation unit. However, whereas the flash zone of an atmospheric column may be at 14 psi to 18.5 psi (760-957 mm), the pressure in a vacuum column is very much lower, generally

less than 0.8 psi (less than 40 mm Hg) in the flash zone to less 0.2 psi (less than 10 mm Hg) at the top of the vacuum tower. The vacuum heater transfer temperature is generally used for control, even though the pressure drop along the transfer line makes the temperature at that point somewhat meaningless. The flash zone temperature has much greater significance.

The distillation of high-boiling feedstocks may require pressures as low as 0.29-0.58 psi (15-30 mm Hg), but operating conditions are more usually 0.97-1.93 psi (50-100 mm Hg). Volumes of vapor at these pressures are large, and pressure drops must be small to maintain control, so vacuum columns are necessarily of large diameter. Differences in vapor pressure of different fractions are relatively larger than for lower boiling fractions, and relatively few plates are required. Under these conditions, a heavy gas oil may be obtained as an overhead product at temperatures of approximately 150°C (300°F). Lubricating oil fractions may be obtained as sidestream products at temperatures of 250 to 350°C (480 to 660°F). The feedstock and residue temperatures being kept below the temperature of 350°C (660°F), above which the rate of thermal decomposition (cracking) increases. The partial pressure of the hydrocarbons is effectively reduced yet further by the injection of steam. The steam added to the column, principally for the stripping of bitumen in the base of the column, is superheated in the convection section of the heater.

Distribution in the Environment

The movement of released chemicals into the Earth systems is caused by transport, dispersion, and deposition of the chemicals (or, in some cases transformed chemicals). Transport is movement caused by a time-averaged flow while dispersion results from local factors and deposition processes, including precipitation, scavenging, and sedimentation which ultimately move (for example) atmospheric chemical pollutants to the water and land surfaces of the Earth.

Furthermore, the distribution of chemical in the environment is influenced by the physical properties of the chemicals and the minerals (such as the clay minerals) with which the chemicals come into contact. However, the movement of chemicals through the environment is complex and is difficult to predict. Different types of chemicals react differently with soils, sediments, and other geologic materials and commonly travel along different flow paths and at different velocities. For example, using soil as the example, contaminants that are highly soluble, such as salts (e.g., sodium chloride, NaCl) move readily from surface soils to saturated materials below the water table. This often occurs during and after rainfall events.

Other contaminants that are not highly soluble may have considerably longer residence times in the soil zone. Some contaminants adsorb readily onto soil particles and slowly dissolve during precipitation events, resulting in dissolved fraction concentrations of contaminants migrating to groundwater. Once below the water table, chemicals are also subject to dispersion (mechanical mixing with uncontaminated water) and diffusion (dilution by concentration gradients).

Typically, chemicals released from various sources are ultimately dispersed among, and can at times accumulate in, various environmental compartments (such as soil as well as various floral and faunal species). Some contaminants may contribute primarily to environmental compartments on a local scale, but other contaminants that are more persistent in the environment can be distributed over much greater distances – even up to a regional scale, a national scale, or an international scale.

Thus, understanding the potential environmental impact of dispersed chemicals requires an understanding of the relative contribution of the various sources of the pollutants as well as the types of the and the potential for a pollutant to undergo chemical (or physical) transformation in the environment. Therefore, an investigation of a potential contaminant must account for transport of the contaminant through ecosystems. The required characterization of concentrations of contaminants in an environmental medium, such as air, involves accounting for the gains (or inputs to) and losses from that medium, and transport through it.

Some examples of atmospheric pollutants include nitrogen dioxide (NO₂), sulfur dioxide (SO₂), and carbon monoxide (CO). The first two pollutants combine with water to form acids, which not only irritate the lungs but also contribute to the long-term destruction of the environment due to the generation of acid rain.

Carbon monoxide, generated by the incomplete combustion of hydrocarbons, displaces and prevents oxygen from binding to hemoglobin and causes asphyxiation. Also, it binds with metallic pollutants and causes them to be more mobile in air and water.

Fresh, clean, and drinkable water is a necessary but limited resource on the planet. Industrial, agricultural, and domestic wastes can contribute to the pollution of this valuable resource, and water pollutants can damage human and animal health. Three important classes of water pollutants are heavy metals, pollutants, and organic pollutants. Heavy metals include transition metals such as cadmium, mercury, and lead, all of which can contribute to brain damage. pollutants like hydrochloric acid, sodium chloride, and sodium carbonate change the acidity, salinity, or alkalinity of the water, making it undrinkable or unsuitable for the support of floral and faunal species.

The use of pesticides (such as phosphates) in agriculture contributes to environmental pollution. Pesticides are used to control the growth of insects, weeds, and fungi, which compete with humans in the consumption of crops. This use not only increases crop yields and decreases grocery prices, but also controls diseases such as malaria and encephalitis. However, the spraying of crops and the water runoff from irrigation transports these harmful chemicals to the habitats of nontarget animals. Chemicals can build up in the tissues of these animals, and when humans consume the animals, the increased potency of the pesticides is manifested as health problems and in some cases death. Chemists have recently developed naturally occurring pesticides that are toxic only to their particular targets and are benign to birds and mammals. The most significant pesticide of the twentieth century was DDT (dichloro-diphenyl-trichloroethane), which was highly effective as an insecticide but did not break down in the environment and led to the death of birds, fish, and some humans.

DDT

In order to take account of the multimedia nature of pollutant transport, assessments usually examine multiple pathways that define the movement of a pollutant from a source, through a linear sequence of environmental compartments, to a receptor. An example of a particular pathway is a source emitting a pollutant to air (an air compartment), transport of the pollutant to the air above a field (another air compartment), deposition on vegetation (a vegetation compartment), eating of the vegetation by cows (an animal compartment), and drinking by humans of the milk from cows (a receptor, exposed by the ingestion route). The pathway may be elaborated to almost any arbitrary degree, depending on how it is to be evaluated. For example, the deposition of a pollutant from air to vegetation may incorporate additional air compartments like a boundary layer of air around the vegetation, and the laminar flow layer of air above the vegetation.

The most appropriate method for assessing the environmental transport of a specific substance depends on the linearity of the physical and chemical processes involved in pollutant transport with respect to pollutant concentrations in each compartment—fluxes between compartments usually depend linearly on the concentrations in connected compartments. If this linearity holds, a transport network through multiple compartments may be represented by the linear super-position of non-self-intersecting pathways. Where nonlinearities occur, the approach becomes less useful, and all compartments may have to be examined simultaneously, although it sometimes may be possible to contain all the nonlinearities within the more complex components of single pathways.

To effectively monitor changes in the environmental behavior of chemicals that are of most concern, it is extremely important to understand how these chemicals typically behave in natural systems and in specific ecosystems. Equally important is an understanding of how these chemicals might respond to specific best management practices. Some of the discharged chemicals only become problems at high concentrations that impair the beneficial uses of these ecosystems. An effective monitoring program explicitly considers how these chemicals may change as they move from a source into the groundwater, surface water, or into the soil. This includes an understanding of how a specific chemical may be introduced or mobilized within an ecosystem, how the chemical moves, or through an ecosystem, the transformations that may occur during this process.

As an example, groundwater will normally look clear and clean because the ground naturally filters out particulate matter. However, natural and manufactured chemicals can be found in groundwater. As groundwater flows through the ground, metals such as iron and manganese are dissolved and may later be found in high concentrations in the water. Industrial discharges, urban activities, agriculture, groundwater pumpage, and disposal of waste all can affect groundwater quality. Pollutants can be anthropogenic in origin such as chemicals from leaking fuel tanks or toxic chemical spills. Pesticides and fertilizers applied to lawns and crops can accumulate and migrate to the water table. Also, leaks from septic tanks and/or waste disposal sites can introduce bacteria to the water, and pesticides and fertilizers that seep into farmed soil can eventually end up in water drawn from a well. On the other hand, a well might have been placed in land that was once used for something like a garbage or chemical dump site.

However, the entry of chemicals into the environment and the distribution of these chemicals within the environment are often complex, and there have been many occasions when a significant amount of a chemical (or a mixture of chemicals) has entered an ecosystem and the effects of contamination are well defined. Generally, the assumption is that the chemical (or a mixture thereof) does not rapidly diffuse away, but remains in the immediate vicinity at a noticeably high concentration or perhaps moves, but in such a way that concentration levels of the chemical remain high as it moves. Such cases would normally occur when large quantities of a substance were being stored, transported, or otherwise handled in concentrated form. Thus, due to leakages, spills, improper disposal, and accidents during transport, compounds that have become subsurface contaminants that threaten various.

Background knowledge of the sources, chemistry, and potential risks of toxic heavy metals in contaminated soils is necessary for the selection of appropriate remedial options. Remediation of soil contaminated by heavy metals is necessary to reduce the associated risks, make the land resource available for agricultural production, enhance food security, and scale down land tenure problems. Immobilization, soil washing, and phytoremediation are frequently listed among the best available technologies for cleaning up heavy metal contaminated soils. These technologies are recommended for field applicability and commercialization in the developing countries also where agriculture, urbanization, and industrialization are leaving a legacy of environmental degradation.

Finally, there are methods that can be used to calculate factors available that can be used to understand the entry of chemical in the environment and the method of dispersal. For example, the amount of a pollutant available for exposure depends on its persistence and the potential for its bioaccumulation as well as the exposure route.

By way of explanation, an exposure route refers to the way that a released chemical enters the flora and fauna as a result of the release. The route of the potential uptake of the chemical is an important attribute of an exposure event.

In addition, any chemical (including both organic chemicals and inorganic chemicals) that is introduced into the environment can be considered to be capable of accumulation (or bioaccumulation) if the chemical has a degradation

half-life in excess of thirty days or if the chemical has a bioconcentration factor (BCF) greater than 1,000 or if the $\log K_{ow}$ (the octanol-water partition coefficient of the chemical) is greater than 4.2:

$$BCF = (\text{concentration in biota})/(\text{concentration in ecosystem})$$

The octanol/water partition coefficient (K_{ow}) is the ratio of the concentration of a chemical in the octanol phase relative to the concentration of the chemical in the aqueous phase of a two-phase octanol/water system:

$$K_{ow} = (\text{concentration in octanol phase})/(\text{concentration in aqueous phase})$$

The bioconcentration factor (BCF) indicates the degree to which a chemical may accumulate in biota (flora and fauna). However, measurement of bioconcentration is typically made on faunal species and is distinct from transport in the food chain, bioaccumulation, or biomagnification. The bioconcentration factor is a constant of proportionality between the chemical concentration in flora or fauna in an ecosystem. It is possible, for many chemicals, to estimate the bioconcentration factor from the octanol-water partition coefficients (K_{ow}):

$$\text{Log}(\text{bioconcentration factor}) = m\log K_{ow} + b$$

In terms of actual numbers, for many lipophilic chemicals, the bioconcentration factor can be calculated using the regression equation:

$$\log BCF = -2.3 + 0.76 \times (\log K_{ow})$$

Furthermore, empirical relationships between the octanol-water partition coefficients and the bioconcentration factor can be developed on a chemical-by-chemical basis.

Indeed, an analysis of the amount of chemical waste formed in processes for the manufacture of a range of fine chemicals and chemical intermediates has revealed that the amount of waste generated in some processes may be in excess of the amount of the desired product and such overproduction of waste was not exceptional in the chemical industry. As a means of measuring the amount of waste vis-à-vis the amount of products, the E-factor (environmental factor) (kilograms of waste per kilogram of product) was introduced as an indication of the environmental footprint of the manufacturing process in various segments of the chemical industry. This factor is derived from the chemicals and fine chemicals industries as a measure of the efficiency of the manufacturing process: Thus, simply:

$$E = \text{kilograms of waste/kilogram of product}$$

The factor can be conveniently calculated from a knowledge of the number of tons of raw materials purchased and the number of tons of product sold, the calculation being for a particular product or a production site or even a whole company. A higher E-factor means more waste and, consequently, a larger environmental footprint – thus, since mass cannot be created resulting in a negative E-factor, the ideal E-factor for any process is zero.

However, in the context of environmental protection and to be all inclusive, the E-factor is the total mass of raw materials plus ancillary process requirements minus the total mass of product, all divided by the total mass of product. Thus, the E-factor should represent the *actual amount* of waste produced in the process, defined as everything but the desired product and takes the chemical yield into account and includes reagents, solvent losses, process aids, and (in principle) even the fuel necessary for the process. Moreover, use of the E-factor has been widely adopted by many of the chemical industries and the pharmaceutical industries in particular. Thus, a major aspect of process development recognized by process chemists and by process engineers is the need for determining an E-factor – whether or not it is called by that name (i.e., the E-factor), but *chemicals in compared to chemical out* has become a major yardstick in many of the chemicals industries.

In terms of properties and transportation of the chemical, particulate matter occupies a somewhat different place to the more conventional chemical contaminants insofar as the transport characteristics of particles depend on the particle size. Fine and coarse particles in ambient air differ in their chemical composition, solubility, acidity, sources and formation processes, atmospheric lifetime, infiltration indoors, and transport distances. Most airborne particles are quite small (less than $0.1\text{ }\mu\text{m}$ in diameter, $0.2\text{ }\mu\text{m}$; $1\text{ }\mu\text{m} = 1\text{ meter} \times 10^{-6}$), but most of the particle volume (and mass) is found in particles with diameters greater than $0.1\text{ }\mu\text{m}$. The size distribution of airborne particles is often multimodal.

Fine particles are usually defined as those having an aerodynamic diameter less than $2.5\text{ }\mu\text{m}$. Fine and coarse particles generally have distinct sources and formation mechanisms, although there may be some overlap. Fine particles are usually formed from gases in two ways: (i) nucleation, which involves the formation of new particles from low vapor pressure chemicals present in vapor form, produced either from combustion or from chemical reaction of gases and (ii) condensation of gases onto existing particles. Particles formed from nucleation also coagulate to form relatively larger particles, although particles normally do not grow above $1.0\text{ }\mu\text{m}$ in aerodynamic diameter by these processes.

Particles formed as a result of the chemical reaction(s) of gases (which are secondary particles because the direct emission from a source is a gas such as sulfur dioxide, SO_2 , or nitric oxide, NO) that is subsequently converted to a low vapor pressure substance (such as sulfuric acid or nitric acid) that subsequently nucleates or condenses. Examples include sulfates, some low volatile organic compounds, and ammonium salts.

Such transformations can take place locally, during prolonged stagnations of ambient air, or during transport over long distances, and are affected by moisture, sunlight, temperature, and the presence or absence of fogs and clouds. In general, particles formed from these types of secondary processes will be more uniform in space and time than those that result from primary emissions. Particles directly emitted by sources, referred to as primary particles, are also found in the fine particle fractions (the most common being particles from combustion sources that are less than $1.0\text{ }\mu\text{m}$ in aerodynamic diameter). In contrast to fine particles, most of the coarse particle fraction of ambient aerosol originated as particles emitted directly to the atmosphere, and some particles generated during combustion processes, such as fly ash and soot, might also be found in the coarse fraction.

Every particle in the atmosphere tends to settle to the ground through the effects of gravity, but the tendency to settle is opposed or abetted by other effects including electrostatic and aerodynamic forces. The outcome is that particles deposit to the ground at velocities that depend primarily on their particle diameter and density. For coarse particles, controlled primarily by gravity, the deposition velocity is proportional to the square of the particle diameter. For fine particles, deposition is controlled more by electrostatic and other effects than by gravity, so that they deposit more rapidly than would be expected from gravity and their size alone. The result is that fine particles with an aerodynamic diameter between 0.1 and $1.0\text{ }\mu\text{m}$ have the minimum deposition velocity of particles. Such fine particles will remain suspended for much longer times (on the order of days to weeks for fine particles as opposed to minutes to hours for coarse particles) and will travel much farther (as far as thousand miles) than the coarse particle fraction.

Domestic Waste

Waste is the remains or by-product from a process for which no use is planned or foreseen. The words domestic (or municipal) and industrial are qualifiers of the source of the waste and, to some extent, also descriptive of the contents of the waste. Once a material has been designated as waste, it remains waste until it has been fully recovered and no longer poses a potential threat to the environment.

Thus, domestic waste (also known as rubbish, garbage, trash, or junk) is unwanted or undesired material. Waste is the general term; though the other terms are used loosely as synonyms, they have more specific meanings: rubbish or trash are mixed household waste including paper and packaging; food waste or garbage (North America)

is kitchen and table waste; and junk or scrap is metallic or industrial material that contribute to organic waste (Table D-4).

Table D-4 Examples of the types of organic chemical waste.

Source	Waste type
Chemical manufacturing	Spent solvents
	Reactive materials
Cleaning agents	Spent solvents
Construction industry	Spent solvents
Cosmetics manufacturing	Ignitable materials
	Flammable solvents
Crude oil recovery and refining	Drilling mud spills
	Spilled solvents
	Process sludge
Furniture manufacturing and refinishing	Ignitable materials
	Spent solvents
Leather products	Waste solvents
Power generation	Gases and coal dust
	Combustion waste (ash and slag)
Printing industry	Spent solvents
Vehicle maintenance	Ignitable materials
	Spent solvents

There are other categories of waste as well: sewage, ash, manure, and plant materials from garden operations, including grass cuttings, fallen leaves, and pruned branches.

See: Industrial Waste, Waste.

Downdraft Combustion

Down-draught combustion is a method of controlling the emission of smoke which involved inversion of the simple coal fire. Air enters at the top of the container, and combustion products leave at the bottom; an important technical feature is that the flame front travels in the opposite direction of the primary air. In this type of system, volatile matter which was evolved ahead of the flame front would be swept back by the air stream through the flame and into the incandescent part of the bed, where it is combusted thereby reducing its contribution to the pollutants.

One feed system for this combustor is the underfeed stoker in which the fuel is fed by a worm feeder into the bottom of a retort. The fuel rises vertically in the retort and air enters through tuyeres in the sides. The fire is ignited at the top, and the flame front moves downward, and its speed is matched by the rising flow of coal, fulfilling the requirement of the flame front traveling in the opposite direction of the primary air. Volatile matter from the coal mixes with the air and ignites as it passes through the incandescent top layer of the bed thereby effectively controlling smoke emission.

Another feed system is the chain-grate stoker in which the fuel is fed from hoppers by gravity to a grate which consists of an endless chain extending into the boiler. The horizontal movement of the grate carries the fuel into the combustion chamber; the coal is carried forward as a thin layer on the top surface of the grate while air is delivered beneath it. As the fuel enters the combustion chamber, the top surface is ignited by radiation from a hot refractory arch, and the flame front then travels down through the coal bed, while the air comes up through it. At the end of the grate, the fuel has been burned and any residual ash is dropped into a container as the grate turns for the return journey.

See also: Combustion.

Downdraft Gasifier

By the conventional downdraft gasifier (co-current gasifier), biomass is fed at the top of the reactor and air intake is at the top or from the sides.

The gas leaves at the bottom of the reactor, so the fuel and the gas move in the same direction. The pyrolysis gasses are led through the oxidation zone (with high temperatures) and are more or less burnt or cracked. Therefore, the producer gas has low tar content and is suitable for engine applications. In practice, however, a tar-free gas is seldom if ever achieved over the whole operating range of the equipment. Because of the lower level of organic components in the condensate, downdraft gasifiers suffer less from environmental objections than updraft gasifiers.

The co-current fixed bed (down draft) gasifier is similar to the counter-current type, but the gasification agent gas flows in co-current configuration with the fuel (downwards, hence the name down draft gasifier). Heat needs to be added to the upper part of the bed, either by combusting small amounts of the fuel or from external heat sources. The produced gas leaves the gasifier at a high temperature, and most of this heat is often transferred to the gasification agent added in the top of the bed, resulting in energy efficiency on level with the counter-current type. Since all tars must pass through a hot bed of char in this configuration, tar levels are much lower than the counter-current type.

The drawbacks of the downdraft gasifier are (i) the high amounts of ash and dust particles in the gas, (ii) the inability to operate on a number of unprocessed fuels; often, pelletization or briquetting of the biomass is necessary, (iii) the outlet gas has a high temperature leading to a lower gasification efficiency, and (iv) the moisture content of the biomass must be less than 25 %.

See: Gasifiers, Gasification.

Downflow Fixed Bed Reactor

This reactor design commonly used in hydrodesulfurization of distillates is the fixed-bed reactor design in which the feedstock enters at the top of the reactor and the product leaves at the bottom of the reactor.

The catalyst remains in a stationary position (fixed-bed) with hydrogen and crude oil feedstock passing in a downflow direction through the catalyst bed. The hydrodesulfurization reaction is exothermic, and the temperature rises from the inlet to the outlet of each catalyst bed. With a high hydrogen consumption and subsequent large temperature rise, the reaction mixture can be quenched with cold recycled gas at intermediate points in the reactor system. This is achieved by dividing the catalyst charge into a series of catalyst beds, and the effluent from each catalyst bed is quenched to the inlet temperature of the next catalyst bed.

The extent of desulfurization is controlled by raising the inlet temperature to each catalyst bed to maintain constant catalyst activity over the course of the process. Fixed-bed reactors are mathematically modeled as plug-flow reactors with little back mixing in the catalyst beds. The first catalyst bed is poisoned with vanadium and nickel at the inlet to the bed and may be a cheaper catalyst (*guard bed*). As the catalyst is poisoned in the front of the bed, the temperature exothermic moves down the bed and the activity of the entire catalyst charge declines, thus requiring a raise in the reactor temperature over the course of the process sequence.

After catalyst regeneration, the reactors are opened and inspected, and the high metal content catalyst layer at the inlet to the first bed may be discarded and replaced with fresh catalyst. The catalyst loses activity after a series of

regenerations and, consequently, after a series of regenerations, it is necessary to replace the complete catalyst charge. In the case of high metal content feedstocks (such as residua), it is often necessary to replace the entire catalyst charge rather than to regenerate it. This is due to the fact that the metal contaminants cannot be removed by economical means during rapid regeneration and the metals have been reported to interfere with the combustion of carbon and sulfur, catalyzing the conversion of sulfur dioxide (SO_2) to sulfate (SO_4^{2-}) that has a permanent poisoning effect on the catalyst.

Fixed-bed hydrosulfurization units are generally used for distillate hydrosulfurization and may also be used for residuum hydrosulfurization but require special precautions in processing. The residuum must undergo two-stage electrostatic desalting so that salt deposits do not plug the inlet to the first catalyst bed, and the residuum must be low in vanadium and nickel content to avoid plugging the beds with metal deposits, hence the need for a guard bed in residuum hydrosulfurization reactors.

During the operation of a fixed-bed reactor, contaminants entering with fresh feed are filtered out and fill the voids between catalyst particles in the bed. The buildup of contaminants in the bed can result in the channeling of reactants through the bed and reducing the hydrosulfurization efficiency. As the flow pattern becomes distorted or restricted, the pressure drop throughout the catalyst bed increases. If the pressure drop becomes high enough, physical damage to the reactor internals can result. When high-pressure drops are observed throughout any portion of the reactor, the unit is shut down and the catalyst bed is skimmed and refilled.

With fixed-bed reactors, a balance must be reached between reaction rate and pressure drop across the catalyst bed. As catalyst particle size is decreased, the desulfurization reaction rate increases but so does the pressure drop across the catalyst bed. Expanded-bed reactors do not have this limitation, and small 1/32 inch (0.8 mm) extrudate catalysts or fine catalysts may be used without increasing the pressure drop.

Drizo Process

The Drizo process is a glycol dehydration process in which the glycol is regenerated by solvent stripping instead of the conventional gas stripping. Solvent stripping allows much higher glycol purities than gas stripping (up to 99.99% w/w instead of the typical 99.95 wt%) and consequently allows to get much larger water dew point depressions: up to 100°C (180°F) and even higher in some cases. The solvent required by the Drizo process is usually an aromatic (BTEx-type) solvent, and in most cases, the process will even produce some liquid hydrocarbon derivatives.

The glycol dehydration option is an example of a process that provides absorption dehydration, and in the process, a liquid desiccant provides the means to absorb water from the gas stream. Ethylene glycol ($\text{HOCH}_2\text{CH}_2\text{OH}$) was, initially, the principal chemical agent in this process, has a strong affinity for water, and when the glycol is in contact with a stream of water-wet natural gas, the ethylene glycol absorbs the water from the gas stream. Initially, the process used ethylene glycol as the absorbent, but, with the advancement of the technology, glycol dehydration now involves the use of an aqueous solution of a glycol derivative in which the glycol is either diethylene glycol (DEG) or triethylene glycol (TEG), which is brought into contact with the water-wet gas stream in a contactor.

The glycol solution will absorb water from the wet gas, and once absorbed, the glycol sinks to the bottom of the contactor while the natural gas, stripped of most of the water content, is then transported out of the dehydrator. The glycol solution, bearing all of the water stripped from the natural gas, is put through specialized equipment that is designed to vaporize only the water out of the solution where the boiling point differential facilitates removal of the water which makes it relatively easy to remove water from the glycol solution after which the glycol is recycled to the contactor.

The process regenerates the glycol by solvent stripping instead of the conventional gas stripping. Solvent stripping allows to obtain much higher glycol purities than gas stripping (up to 99.998 wt% instead of the typical 99.95 wt%) and consequently allows to get much larger water dew point depressions: up to 100°C (180 Glycol solvent stripping by condensates (instead of conventional gas stripping) allows (i) higher glycol purities down to < 1 ppmv water in treated gas, and (ii) reduced carbon dioxide emissions. The solvent required by the Drizo process is usually obtained from the BTEx present in many gas streams itself, and in most cases, the process will even produce some liquid hydrocarbons.

Drop Tube Furnace

A drop tube furnace (vertical tube furnace) is used for devolatilization and char combustion tests. The sample of the feedstock is injected into a hot (up to 1,500°C, 2,730°F) downward gas stream under laminar flow conditions for residence times up to 500 milliseconds. A gas mixing facility allows use of oxidizing or reducing atmosphere.

It is important to predict the combustion behavior of solid fuels such as biomass and biochar before their use in industrial equipment. The drop tube furnace can also be used to determine the events during the pyrolysis of biomass (for example, sawdust and pinewood, 120 to 250 μm size) at temperatures of up to 1,450°C (2,640°F) in both carbon dioxide and nitrogen atmospheres.

Typically, the furnace is electrically heated and is able to work at a maximum temperature of 1,300°C (2,375°F). The combustion chamber is a cylindrical ceramic tube with an inner diameter of 35 mm and a length of 1.75 m. The furnace wall temperatures are continuously monitored by thermocouples distributed along the combustion chamber. A water-cooled injector, placed at the top end of the drop tube furnace, is used to feed the pulverized grape pomace and the air to the combustion chamber. A twin-screw volumetric feeder transfers the pulverized-coal to an ejector system from which the particles are air-transported to the injector. The transport and secondary air are supplied by an air compressor (150 psi), with the flow rates being measured using mass flow controllers.

Dry-Ash-Free Basis

Dry-ash-free basis (daf basis) refers to the data from analysis calculated as if moisture and ash were removed.

The final results of the proximate analysis of carbonaceous materials are usually reported to the first decimal place; any subsequent figures have little or no significance. The final report of the analysis should always contain the results on a basis of air-dried fuel (i.e., the feedstock in its most stable condition and in which it was analyzed), but for purposes of classification or comparison, it is often necessary to convert to another basis such as dry feedstock, dry-ash-free feedstock, or as received feedstock. This allows comparison of the data on a basis that is not influenced by water or mineral matter content.

The analyses of a feedstock may be reported on different bases with regard to moisture and ash content. Thus, results that are *as determined* refer to the moisture condition of the sample during analyses in the laboratory; a frequent practice is to air-dry the sample, thereby bringing the moisture content to approximate equilibrium with the laboratory atmosphere in order to minimize gain or loss during sampling operations. Loss of weight during air-drying is determined to enable calculation on an *as-received* basis (the moisture condition when the sample arrived in the laboratory). This is, of course, equivalent to the *as-sampled* basis if no gain or loss of moisture occurs during the transportation to the laboratory from the sampling site. Attempts to retain the moisture at the *as-sampled* level include shipping in sealed containers with sealed plastic liners or in sealed plastic bags.

Analyses reported on a *dry* basis are calculated on the basis that there is no moisture associated with the sample. The moisture value is used for converting the *as determined* data to the *dry* basis. Analytical data that are reported on a *dry, ash-free* basis are calculated on assumption that there is no moisture or mineral matter associated with the sample. The values obtained for moisture determination and ash determination are used for the conversion.

The mineral matter in a feedstock loses weight during thermal conversion to ash because of the loss of water of constitution of clays, and the loss of carbon dioxide from carbonate minerals such as calcite. In addition, any chlorine in the feedstock is converted to hydrogen chloride but the change in weight may not be significant. Analyses and calorific values are determined on a mineral matter-free basis and the data presented with corrections for the mineral matter.

See also Proximate Analysis.

Dry Deposition

Dry deposition refers to the removal of both particles and gases as they come into contact with the land surface. The process is efficient as only a few gases (most notably carbon dioxide) show signs of global increase in spite of

the large emission of pollutants from both natural and anthropogenic sources. There are two types of deposition mechanisms: (i) dry deposition, which is the uptake at the surface of the Earth in the soil, a water system, or in vegetation, and (ii) wet deposition, which is formation of droplets followed by droplet precipitation (such as by rain) or impaction on the surface of the Earth (as, for example, fog droplets).

Also, often included in the category of dry deposition is the phenomenon known as gravitational sedimentation which occurs during periods without precipitation. These particles include (i) aerosols, (ii) sea salts, (iii) particulate matter, and (iv) adsorbed/reacted gases captured by vegetation. Related to this is the impaction is the capture of particles moving horizontally in the airstream by the vegetation canopy which (as a filtering effect) may accumulate large quantities of nutrients in some environments. On the other hand, wet deposition is the removal of pollution plume components by the action of rain. The wet deposition of radionuclides in a pollution plume by rain often forms so-called *hot spots* of radioactivity on the underlying surface.

Drying

At some stage of the production of any gaseous, liquid, and solid fuels, the feedstock and the products will, of necessity, need to be dried (i.e., the water will have to be removed).

Drying of the biomass fuel is advisable if fresh wet materials (moisture content 50-60% on wet basis) are to be gasified. Lowering the moisture content of the feedstock is associated with a better performance of the gasifier. Utilizing the exhaust gases from an internal combustion engine is a very efficient way to do so. The sensible heat in engine exhaust is sufficient to dry biomass from 70% down to 10%. Rotary kilns are the most applied dryers. The energy costs of drying are high, but these can be outweighed by the lower downstream gas cleaning requirements for dried feed.

In combustion systems, any water content in the fuel must be driven off before the first stage of combustion can occur, requiring energy, and thus reducing overall system efficiency and potentially reducing combustion temperature below the optimum. Reduction in combustion temperature below the optimum may result in incomplete combustion of the fuel giving rise to the emission of tars and creosote which may condense in the flue, especially if it is long or includes changes of direction, and particulates. The water may also condense in the flue, and all these may lead to corrosion of the flue and the gradual accretion of material leading to the potential for eventual blockages or fire.

Dryers can be broadly divided into two categories based on how heat is provided for drying. In direct dryers, the material gets heat from direct contact with a fluid providing the heat—either hot air or hot steam. With indirect drying, the material being dried is separated from the heat source by a heat exchange surface. One important consequence of indirect drying is that it is possible to recover the latent heat of evaporated water because the water vapor is not diluted by air. This can be done by drawing a vacuum on the material as it is drying and condensing the water vapor before a vacuum pump, or if the dryer is operated at a sufficiently high temperature, the water evaporates at an elevated pressure.

Directly heated dryers can be further divided into two more categories: air and superheated steam dryers (SSDs). In air dryers, hot air is contacted with the material to be dried. The air loses its sensible heat and provides the latent heat of evaporation to dry the material. The air also removes the water vapor that is evaporated. The material can be agitated by some mechanical means or by the flowing air.

In superheated steam dryers, the heating fluid is steam rather than air, but the concept is the same. The superheated steam is contacted with the biomass material and loses some of its sensible heat to provide the latent heat of evaporation to dry the fuel. The steam, however, remains above its saturation temperature, so it does not condense. The water vapor leaving the biomass is heated by the superheated steam, so the net result is a larger amount of steam at a lower temperature than when the steam entered the dryer. The excess steam is removed, and the remainder is reheated and recycled back to the dryer.

In the case of the indirectly heated dryer operated under a vacuum, or with a superheated steam dryer, the latent heat of evaporation of the water vapor is easy to recover because it is not diluted by air. With vacuum drying, this

heat is available only at a low temperature, but with superheated steam drying, the dryer can be designed to produce steam at practically any pressure for use in other parts of the plant.

There are several steps to drying – first, the material must be heated from the temperature at which it entered the dryer, up to the wet bulb temperature, to produce a driving force for water to leave the wet material. Next, any surface moisture on the material is evaporated—this occurs fairly quickly. Once all the surface moisture is removed, the material must be heated to drive water from the inside of the biomass to the surface so it can evaporate. This occurs during the falling rate period when the rate of drying drops as the material becomes drier. During the falling rate period, the surface temperature of the material remains close to the wet bulb temperature. Once the material is completely dry, it begins to heat up to the surrounding temperature, because water is no longer present to keep its temperature low.

There are two points in the drying process when there is a significant fire risk. The first occurs after the surface moisture has evaporated, but before an appreciable amount of water has been driven out from inside the biomass. During this very brief period, there is no water vapor near the surface to keep the fuel particle cool, and the surface can quickly heat up while the inside remains cool. If the surface remains hot for a long enough time, the material can ignite even if it is not completely dry. However, once the inside of the particle starts to drive water to the surface, a constant supply of moisture moving to the surface will keep it cool until it is completely dry.

The other time when fire is a concern is when material is over-dried. If the material loses all its moisture, it will begin to warm and can ignite when it reaches its combustion temperature, or when any gases evolved reach their flash point. Since the drying rate drops as biomass material gets drier, most dryers are not designed to completely dry the material. Over-drying would be expected to occur only during upset conditions or when processing a material with better drying properties than what the dryer was designed to handle.

The drying equipment can be further characterized according to the bed types used in the drying process which are (i) static bed, (ii) moving bed, (iii) fluidized bed, (iv) dilute bed, and (v) parallel flow equipment.

A *static bed* is a dense bed of particles with the particles resting on each other at the settled bulk density, and there is no relative motion among the solid particles. This would be typically encountered in a tray dryer where the solids are contained in a tray over which the drying gas flows. A *moving bed* is a slightly expanded bed where the particles can flow over one another. The flow can be induced either by gravity or by mechanical agitation. A *fluidized bed* is in an expanded condition where the upward superficial velocity above the bed is not high enough to carry the particles out of the reactor. However, the higher velocity due to the presence of the solids inside the denser fluidized bed is sufficient to drag the particles upward and greatly expand the bed even though not high enough to carry the particles out of the containment vessel. A *dilute bed* is in a fully expanded condition where the solid particles are so far apart that they have no influence on each other. Usually, the gas velocity is above the terminal settling velocity of the particles and the particles are carried out of the vessel with the gas. In the *parallel flow* equipment, the parallel flow occurs when the gas flow is parallel to the surface of the solids bed. The solids bed is usually in a static condition, and the contacting is primarily at the interface between the solids and gas. A small amount of gas penetration into the voids among the particles at the surface can occur. Perpendicular flow occurs when the gas flow is perpendicular to the surface of the solids. The solids bed is again usually in the static condition, and the gas impinges on its surface. Circulation occurs when the gas penetrates the bed and flows through the interstices among the solids more or less freely around the individual particles which can occur with solids beds in either the static, moving, fluidized, or dilute condition. The flow of gas can be either *cocurrent* with the solids, *countercurrent* against the flow of the solids, or *cross-current* perpendicular to the flow of the solids.

See: Biomass, Biomass – Feedstocks.

Dry Point

The dry point is the temperature at which the last drop of a liquid fuel evaporates in a distillation test.

In the corrected thermometer reading that is observed at the instant the last drop of liquid (exclusive of any drops or film of liquid on the side of the flask or on the temperature sensor) evaporates from the lowest point in the

distillation flask. The end point (final boiling point), rather than the dry point, is intended for general use. The dry point can be reported in connection with special purpose naphtha, such as naphtha used in the paint industry. Also, it is substituted for the end point (final boiling point) whenever the sample is of such a nature that the precision of the end point (final boiling point) cannot consistently meet the necessary requirements.

Dry Sorption Processes

Dry sorption processes are employed to scavenge hydrogen sulfide and organic sulfur compounds (mercaptans) from gas streams through reactions with a solid-based media. They are typically non-regenerable, although some are partially regenerable, losing activity upon each regeneration cycle.

Most dry sorption processes are governed by the reaction of a metal oxide (such as iron oxide and zinc oxide) with hydrogen sulfide to form a metal sulfide compound. For regenerable reactions, the metal sulfide compound can then react with oxygen to produce elemental sulfur and a regenerated metal oxide.

Dry sorption processes can be categorized into two subgroups which are (i) oxidation to sulfur and (ii) oxidation to oxides of sulfur. Since these processes rely on oxidation, gas constituents that cannot be oxidized under the process conditions will not be removed. This is advantageous when dealing with a gas stream where only hydrogen sulfide and, in some cases, carbon dioxide are required to be removed with minimal loss losses of methane due to adsorption. The main product of sulfur oxidation to oxides of sulfur is sulfur dioxide which because this is a controlled exhaust gas, poses a threat to equipment, due to corrosion and poisoning of fuel cell membranes and requires additional gas processing to achieve air discharge standards.

See also: Adsorption.

Dust Collectors

In the biomass-to-fuels industry, the raw biomass typically undergoes a number of crushing, grinding, cleaning, drying, and product sizing operations before (and after) it is converted into a marketable commodity. These operations are highly mechanized, and both individually and collectively, these processes can generate large amounts of dust (particulate matter). If control technologies are inadequate, hazardous levels of respirable dust may be liberated into the work environment, potentially exposing workers. Accordingly, in many countries, regulations are in place to limit the respirable dust exposure of workers. Engineering controls are implemented in many industrial operations in an effort to reduce dust generation and limit worker exposure.

Depending on the size, these particles can become hazardous to worker health, particularly when suspended in air. The largest size particle that can be suspended in air for long periods of time from wind velocity acting upon it is on the order of 60 microns (micrometers, μm). Particles ranging from approximately 60 to 2,000 μm can also become suspended in air, but they only reach heights up to approximately three feet above the ground before they fall back to the surface. Particles larger than approximately 2,000 μm generally creep or roll along the surface due to wind velocity acting upon them. These larger particles of dust can affect the nasal passages, causing an irritated and congested nose, and might also cause an irritant cough should they deposit in the throat. Smaller airborne particles of dust, which can remain suspended in air for hours, pose a greater risk to the respiratory system when inhaled. In general, the smaller the aerodynamic diameter of the inhaled dust particle, the more likely it will be deposited more deeply in the respiratory tract.

Thus, dust collectors (or, for that matter, any type of particulate matter collectors) are used in many processes to either recover valuable granular solid or powder from process streams or to remove granular solid pollutants from exhaust gases prior to venting to the atmosphere. Dust collection is an online process for collecting any process-generated dust from the source point on a continuous basis, and these collectors may be of single unit construction, or a collection of devices used to separate particulate matter from the process air. They are often used as an air pollution control device to maintain or improve air quality. Mist collectors remove particulate matter in the form of fine liquid droplets from the air. They are often used for the collection of metal working fluids, and coolant or oil mists. Mist collectors are often used to improve or maintain the quality of air in the workplace environment. Fume and smoke

collectors are used to remove submicrometer size particulate from the air. They effectively reduce or eliminate particulate matter and gas streams from many industrial processes such as welding, rubber and plastic processing, high speed machining with coolants, tempering, and quenching.

Dust collectors vary widely in design, operation, effectiveness, space requirements, construction, and capital, operating, and maintenance costs but can be generally separated into five common types: (i) an ambient unit, which is a free-hanging system for use when applications limit the use of source-capture arms or ductwork, (ii) a collection booth, which allows the worker greater freedom of movement. they are often portable, (iii) downdraft tables, which form a self-contained portable filtration system that removes harmful particulates and returns filtered air back into the facility with no external ventilation required, (iv) a source collector or portable units which are used for collecting dust, mist, fumes, or smoke at the source, and (v) stationary units – an example of a stationary collector is a baghouse.

More specifically, there are five principal types of industrial dust collectors which are (i) inertial separators, (ii) fabric filters, (iii) wet scrubbers, (iv) electrostatic precipitators, and (v) unit collectors. Thus, systems for fines removal may only contain a single filtration system (such as a filter bag or cartridge). However, most units utilize a primary and secondary separation/filtration system. Furthermore, some units may have third and fourth stage filtration. All separation and filtration systems used within the unit should be specified.

Important parameters in specifying dust collectors include airflow, the velocity of the air stream created by the vacuum producer; system power, the power of the system motor, usually specified in horsepower; storage capacity for dust and particles; and minimum particle size filtered by the unit.

Dust Control

The presence of dust can cause serious problems in many dry cleaning plants and in the pretreatment sections of wet cleaning plants. In addition, dust containment is an integral part of all thermal drying units. The need for dust collection arises because of air pollution control, safety- and health-hazard elimination, and reduction of equipment maintenance costs. In addition to the economic and hazards, coal dust can present serious explosion hazards. Certain bituminous coals and anthracites also continue to release measurable quantities of methane gas for days, and sometimes weeks, after they have been mined, which increases the possibility of explosion. Provision of efficient ventilation and restriction of electrical or thermal sources of ignition are required by regulation.

The main sources of dust emissions are crushers, breakers, dust removers, dry screens, and transfer points between the units in coal pretreatment operations. The size of the coal particles that become airborne generally falls into the range 1 to 100 microns ($1\text{--}100 \times 10^{-6}$ meters), and particles larger than this usually deposit close to the point of origin. It is the usual practice to extract the dust clouds from the various sources through ducts that exhaust to a central air-cleaning unit, although some equipment may include integral dust suppression devices.

Dust collection equipment used at cleaning plants includes (i) dry units such as cyclones, dynamic collectors, and baghouses – also known as fabric filters – and (ii) wet units such as dynamic, impingement, or centrifugal devices, or gravity, disintegrator, or venturi scrubber systems. Other sources of dust are windblown losses from storage piles and from railcars during loading and transportation. Various chemical treatments are available for stockpile sealing and are being used for spraying the tops of railcars; active stockpiles present an almost insurmountable problem.

Dustiness Index

The dustiness index is a means of determining the relative values that represent the amount of dust produced when coal is handled in a standard manner. Dust removal is an important aspect of safety, and there have been constant attempts to improve dust removal technology. As the techniques have been developed, the predictability of how coal will behave, in terms of the dust produced, under certain conditions has also been sought.

To determine the dustiness index, a large sample is placed on a slide plate in a metal cabinet of prescribed size. When the plate is withdrawn, the sample falls into a drawer and, after five seconds, two slides are inserted into the box. The slides collect suspended dust particles for two minutes (coarse dust) or for ten minutes (fine dust).

The dustiness index is reported as forty times the gram weight of dust that has settled after either two minutes or after an additional eight minutes.

Dutch Oven Furnace

A Dutch oven furnace is one of the earliest types of furnaces, having a large, rectangular box lined with firebrick (refractory) on the sides and top, commonly used for burning wood.

Various boiler firing configurations are used for burning wood waste. One common type of boiler used in smaller operations is the Dutch oven. This unit is widely used because it can burn fuels with high moisture content. Fuel is fed into the oven through an opening in the top of a refractory-lined furnace. The fuel accumulates in a cone-shaped pile on a flat or sloping grate. Combustion is accomplished in two stages: (i) drying and gasification, which occurs in the primary furnace, which is separated from the secondary furnace chamber by a bridge wall, and (ii) combustion of the gaseous products in which the combustion is completed in the secondary chamber before gases enter the boiler section. The large mass of refractory helps to stabilize combustion rates but also causes a slow response to fluctuating steam demand. The furnace was commonly used for burning wood. Heat is stored in the refractory lining (firebrick) and radiated to a conical fuel pile in the center of the furnace.

Another type of furnace is the fuel cell oven, in which the fuel is dropped onto suspended fixed grates and is fired in a pile. Unlike the Dutch oven, the refractory-lined fuel cell also uses combustion air preheating and positioning of secondary and tertiary air injection ports to improve boiler efficiency. Because of the overall design and operating similarities, however, the Dutch oven boilers and fuel cell oven boilers have comparable emission characteristics.

See: Combustion.

E85

E85 is an alcohol fuel mixture containing 85% ethanol and 15% gasoline by volume. E85 has an octane rating higher than that of typical rating for regular gasoline of 87, or the rating for premium gasoline of 91 to 94 (Table E-1). This allows it to be used in higher compression engines which tend to produce more power per unit of displacement than their gasoline counterparts.

Table E-1 Examples of the selected properties of E85 and crude oil-based gasoline.

Category	E85	Gasoline
Formula	$\text{CH}_3\text{CH}_2\text{OH}$	C_4 to C_8 (approximately)
Octane number	100	85 to 94
Source	renewable	crude oil
Energy content*	80,000	109,000 to 125,000

*Btu per gallon

The octane number is often derived by using the blending octane value of octane in gasoline. More correctly, the actual octane value of ethanol is 94 to 96 when it is calculated using the research octane number (R) and the motor octane number (M), thus:

$$\text{Octane value} = (\text{R} + \text{M}) / 2.$$

E85 has an octane rating higher than that of regular gasoline's typical rating of 87, or 91 to 93 for premium gasoline. This allows it to be used in higher compression engines which tend to produce more power per unit of displacement than their gasoline counterparts. One complication is that use of gasoline in an engine with a high enough compression ratio to use E85 efficiently would likely result in catastrophic failure due to engine detonation, as the octane rating of gasoline is not high enough to withstand the greater compression ratios in use in an engine specifically designed to run on E85. Use of E85 in an engine designed specifically for gasoline would result in a loss of the potential efficiency that it is possible to gain with this fuel. Using E85 in a gasoline engine has the drawback of achieving lower fuel economy as more fuel is needed per unit air (stoichiometric fuel ratio) to run the engine in comparison with gasoline. This corresponds to a lower heating value (units of energy per unit mass) for E85 than gasoline.

Earth System

The Earth system consists of three main systems (often referred to as spheres) – (i) the atmosphere, which is the gases that surround the Earth, (ii) the aquasphere, which encompasses the water systems of the Earth, and (iii) the geosphere, which is the land systems of the Earth.

The first system, the atmosphere, is an envelope of gas that keeps the planet warm and provides oxygen for breathing and carbon dioxide for photosynthesis. The second system comprises the areas of Earth that are covered with amounts of water, called the aquasphere, and the sub-system, often referred to as the hydrosphere which excludes that part of the aquasphere that contains large quantities of ice at the poles and elsewhere is referred to as the cryosphere.

Then, there is the geosphere which consists of the interior and the surface of Earth, both of which are made up of rocks. The limited part of the planet that can support living flora and fauna comprises part of the geosphere that may also be referred to as the biosphere. Furthermore, the three systems (the aquasphere, the atmosphere, and the geosphere) and the various sub-systems (the hydrosphere, the cryosphere, and the biosphere) are complex systems that interact to maintain the Earth system as it currently exists.

Ebullated Bed Reactor

Ebullating bed technologies were first introduced in the 1960s in an attempt to overcome problems of catalyst ageing and mal-distribution in fixed bed designs. In this approach, hydrogen and feed enter at the bottom of the reactor, thereby expanding the catalyst bed. Although catalyst performance can be kept constant because catalyst can be replaced on line, the ebullated bed results in a back mixed reactor so desulfurization and hydroconversion are less than obtainable in a fixed-bed unit. In some respects, an ebullating bed reactor is a reactor similar to a fluidized bed but operated at higher gas velocities, such that a portion of the solids is carried out with the up-flowing gas.

An ebullated bed reactor (slurry bed reactor) is a type of fluidized bed in which catalyst particles are held in suspension by the upward movement of the liquid reactant and gas flow.

Ebullated bed units, unlike any other hydrotreaters, use a fluidized bed of hydroprocessing catalyst with continuous addition and removal of catalyst to maintain system activity. In ebullated bed reactors, hydrogen-rich recycle gas bubbles up through a mixture of oil and catalyst particles to provide three-phase turbulent mixing. The reaction environment can be nearly isothermal, which improves product selectivity. At the top of the reactor, catalyst particles are disengaged from the process fluids, which are separated in downstream flash drums. Most of the catalyst goes back to the reactor. Some is withdrawn and replaced with fresh catalyst.

Unlike fixed bed residuum catalyst systems, which can use many different catalysts to accomplish specific objectives, ebullated bed units typically use only one catalyst per reactor. That single catalyst must balance the unit requirements for demetallation (demetallization), desulfurization, and conversion.

Depending on the feedstock and the process needs, the ebullated bed can be staged in one or more initial reactors of a series, the product being fed to a subsequent ebullated or fixed bed reactor, or reactors. If desired, an ebullating bed from which aged catalyst is stratified and removed, while fresh or regenerated catalyst is added to the top of the bed, can also constitute the final reactor, or reactors, of the series. The ebullating bed reactor can be employed in series or in parallel.

See also: Ebullated Bed.

Control of sediment formation is the biggest issue in most ebullated bed resid units. When the unit is operated for high conversion, sediment formation increases, which causes problems in downstream equipment and eventual shutdown for cleaning. Albemarle has developed catalysts specifically designed to achieve high conversion activity while controlling sediment at a level which ensure long operating cycles.

The ebullated-bed reactor system overcomes problems encountered with fixed-bed reactors when processing difficult feedstocks (such as heavy crude oil, extra heavy crude oil, and tar sand bitumen) or when high processing severity is required. The bed of extrudate catalyst is fluidized (ebullated) by the lift of hydrogen and feed oil and recycled reactor liquid. The ebullated catalyst is well mixed and can be added and withdrawn from the reactor while at operating conditions.

See also: Fixed Bed Reactor.

Ecological Cycles

The ecological cycles are the various self-regulating processes that recycle the limited resources of the Earth (water, carbon, nitrogen, and other elements) that are essential to sustain life. Understanding how local cycles fit into global cycles is essential to make the best possible management decisions to maintain ecosystem health and productivity for now and the future.

There are biogeochemical cycles for the chemical elements (such as calcium, carbon, hydrogen, mercury, nitrogen, oxygen, phosphorus, selenium, and sulfur) as well as cycles for water and silica; macroscopic cycles such as the rock cycle as well as human-induced cycles for synthetic compounds such as polychlorinated biphenyl derivatives (PCBs). In some cycles, there are *reservoirs* where a substance remains for a long period of time.

There are several ecological cycles that also need a clearer and more detailed definition as each cycle plays an important role in the interrelationship of the various ecological systems to the environment as a whole. These cycles can be perturbed by anthropogenic stress as well as by natural occurrences. For example, the oxygen cycle illustrates the role of oxygen in the land water and air, either as oxygen per se or combined with carbon as carbon dioxide and as mineral carbonate derivatives. The cycle also includes industrial activities (such as fossil fuel burning) and natural activities (represented by volcanic activity). The nitrogen cycle relates not only to nitrogen in the atmosphere but also to nitrogen fixation in the soil and its use in plant growth.

The water cycle (also referred to as the hydrologic cycle) is the means by which water is transported throughout several ecosystems. In theory, there should be a harmonious balance between the water movement on the earth. Indeed, there should be a harmonious balance between the atmosphere, the water systems, and the land systems. But the existence of contrasting desert areas and tropical rain forests speaks to the apparent imbalance in these cycles, particularly in the hydrological cycle. A subcategory of the hydrological cycle involves the dispersion of water in various groundwater systems. These systems are responsible for the availability of water to the various flora and fauna in a particular region. The water availability of water from groundwater systems is considered, perhaps, to be more important than water availability from lakes and rivers. However, the interrelationships of water in the whole hydrological cycle are the most important features of this cycle. For example, the biogeochemical cycle (also called the substance turnover or cycling of substances) is a pathway by which a chemical substance moves through biotic compartments the biosphere) and through abiotic compartments of the Earth (such as the atmosphere, the hydrosphere, and the lithosphere).

The Earth system contains several great cycles in which key materials are transported through the environment. In general, cycles occur in closed systems; at the global scale, many systems may be assumed to be closed because the Earth receives negligible quantities of minerals from space (as a result of meteorite impacts) and because only limited quantities of materials can escape the atmosphere of the Earth.

The biogeochemical cycles operate at the global scale and involve all of the main components of the Earth system in which materials are transferred continually between the atmosphere, the aquasphere, and the geosphere. However, since the biogeochemical cycles involve elements that are essential for life, organisms play a vital part in those cycles. Typically then, the biogeochemical cycles involve an inorganic component (the abiotic part of the cycle, including sedimentary and atmospheric phases) and an organic component (comprising plants and animals, both living and dead). Like other environmental systems, biogeochemical cycles involve the flow of substances between stores (also known as reservoirs) in the geosphere, atmosphere, hydrosphere, and biosphere. Water plays a vital role in mediating many of the flows between stores. Three of the key biogeochemical cycles are the nitrogen, carbon, and sulfur cycles.

The nitrogen cycle is a relatively fast and complex cycle. Most of the atmosphere consists of gaseous nitrogen which is fixed (in other words, made available for use by plants) biologically in soils. Soil bacteria convert nitrogen to ammonia; this, together with inorganic nitrate, is absorbed by plant roots and converted to organic compounds (such as proteins) in plant tissues. These compounds are eaten and consumed by herbivorous animal. In turn, nitrogenous compounds are passed to carnivores, and they are ultimately returned to the soil in the form of nitrogenous waste products (such as urine and fecal matter) and as a result of the death and decomposition of organisms. Bacteria then convert the organic nitrogen compounds into ammonia and ammonium compounds, which are then converted by bacteria into nitrites and then nitrates, which are then available for re-uptake by plants.

Some of the nitrogenous compounds that are not absorbed by plants are leached from the soil into groundwater, surface water, and ultimately into seas and oceans. Of that nitrogenous material, some is used by aquatic plants, some accumulates as organic sediment, and some evaporates into the atmosphere. The cycle is completed by denitrifying bacteria which eventually convert nitrates and nitrites to ammonia, nitrogen, and nitrogen oxides.

The carbon cycle is a cycle in which carbon is stored in the atmosphere in the form of carbon dioxide, which is absorbed by plants and converted to carbohydrates by the process of photosynthesis. The cycle then follows the food chain, with carbohydrates being consumed by herbivores and then carnivores, being metabolized during the process of respiration. Carbon dioxide is returned to the atmosphere as animals exhale and when organic waste and dead

organisms decay. Vegetation and animals are thus important stores of carbon, although that carbon may be rapidly returned to the atmosphere if vegetation is burned. Soils are also important reservoirs for carbon. Atmospheric carbon dioxide is soluble in water, in which it forms carbonic acid, which forms bicarbonate ions and carbonate ions, which in turn form salts (such as the insoluble calcium carbonate, which accumulates in marine sediments, marine organisms, and carbonate rocks, such as limestone). Carbon is typically stored in these forms until it is released to the atmosphere by chemical weathering.

The sulfur cycle is a cycle in which sulfur is released into the atmosphere during volcanic eruptions (in the forms of sulfurous gas, dust, and particles) and as a result of the weathering of rocks. The oceans also play an important role in the sulfur cycle, as marine phytoplankton produce dimethyl sulfide, some of which enters the atmosphere and is converted to sulfur dioxide and sulfate aerosols. These compounds are ultimately converted to sulfuric acid and are deposited on the surface of the Earth as part of the precipitation. In terrestrial ecosystems, bacteria break down sulfurous compounds and release the sulfur to the atmosphere again, mainly in the form of hydrogen sulfide.

Finally, it must be noted that the biogeochemical cycles have been modified substantially by human activities which is necessary for consideration to understand the various environmental issues related to human activities.

See also: Biogeochemical Cycles.

Ecosystem

An ecosystem is a community of living organisms (biotic components) that exists in conjunction with the non-living (abiotic) components of the environment. These biotic and abiotic components are linked together through nutrient cycles, and energy flows such as when energy enters the system and is incorporated into the plant tissues through the photosynthetic process. By feeding on plants (the flora) and on one another, animals (the fauna) play an important role in the movement of matter and energy through the system. This process also influences the quantity of plant biomass and microbial biomass present in the ecosystem.

Thus, an ecosystem works as a unit in an efficient and organized way and receives energy that is passed on through the components of the ecosystem, and, in fact, all life depends on this flow of energy. Green plants (including phytoplankton species) are able to trap the solar energy in an ecosystem, and they make use of this energy for their growth and maintenance. Heterotrophic species (or consumers) obtain the energy requirements from this stored energy (in green plants) as food and use it for their development, growth, maintenance, or other life activities. All life forms in an ecosystem are linked together by the flow of energy. Besides energy, various nutrients and water, which are also required for life processes, are exchanged by the biotic components within themselves and with the abiotic components.

Soil is a critical part of an ecosystem. It provides important nutrients for the plants. It helps anchor the plants to keep them in place. Soil absorbs and holds water for plants and animals to use and provides a home for lots of living organisms. The atmosphere provides oxygen and carbon dioxide for the plants and animals in an ecosystem. The atmosphere is also part of the water cycle. Without the complex interactions and elements in the atmosphere, there would be no life on Earth. The heat and light from the Sun are critical parts of an ecosystem. The heat from the Sun helps water evaporate and return to the atmosphere where it is cycled back into water. The heat also keeps plants and animals warm. The light from the Sun is necessary for photosynthesis, so that plants have the energy they need to make food. Without water, there would be no life. Water is a large percentage of the cells that make up all living organisms. Water is also used by plants to carry and distribute the nutrients they need to survive.

Examples of ecosystems are (i) an agroecosystem, (ii) an aquatic ecosystem, (iii) a coral reef, (iv) a desert, (v) a forest, (vi) a human ecosystem, (vii) a littoral zone, also known as the nearshore which is the part of a sea, lake, or river that is close to the shore, (viii) a marine ecosystem, (ix) prairie, (x) rainforest, (xi) a savanna, (xii) a steppe, (xiii) a taiga, which is the conifer forest that lies between the broad-leaved forest and the tundra, (xiv) a tundra, and (xv) an urban ecosystem. Biomes are globally similar areas, including ecosystems, as regards combinations of plants, animals, soil organisms, and climatic conditions. They have certain common factors, such as plant structures (trees, shrubs, and grasses), leaf types (broadleaf, needles), plant spacing (forest, woodland, savanna), and climate. The basic types of biomes are (i) land, (ii) freshwater, and (iii) marine biomes.

Resource inputs to an ecosystem are generally controlled by external processes such as climate and the parent material in the system, and resource availability within the ecosystem is controlled by internal factors such as decomposition and root competition. Anthropogenic influences also influence the ecosystem.

E-Gas Process

The E-Gas process features a two-stage gasifier design in which the gasifier is refractory-lined and uses coal-water slurry feed. The two-stage gasifier is a coal-water slurry fed, oxygen-blown, refractory-lined gasifier with continuous slag removal system and dry particulate removal. The process is suitable for a wide range of feedstocks.

The first stage of the gasifier has two opposed, horizontally-oriented feed injectors. The synthesis gas exits the top of the first stage, and slag flows out of the bottom into a water bath. The synthesis gas produced by the first stage enters the second stage at temperatures comparable to the exit temperatures of the other two entrained flow gasifiers. Additional coal-water slurry is injected into this hot syngas in the second gasifier stage, but no additional oxygen is injected. Endothermic gasification reactions occur between the hot syngas and the second-stage coal feed. This lowers the temperature of the syngas and increases the cold gas efficiency of the process. Upon exiting the top of the second stage of the gasifier, the syngas passes through a syngas cooler which features a firetube design. The cooled syngas then enters a rigid barrier filter where any unconverted char from the second stage is collected and recycled back to the first stage of the gasifier where the hotter temperatures ensure near complete carbon conversion.

Electrical Energy

Electrical energy is a form of energy resulting from the flow of an electric charge, typically through a wire. Energy is the ability to do work or apply force to move an object which is caused by the movement of charged particles through a wire or other medium called current or electricity.

Electrical energy can be used produce magnetic fields, which can be used to propel motors. It is very transformable and can be used to produce other forms of radiant energy, such as radio waves, microwaves, radiant heat, and light.

The fundamental principle of electricity generation was discovered during the 1820s and early 1830s by Michael Faraday.

In the modern world, electricity is most often generated at a power station by electromechanical generators, primarily driven by heat engines fueled by chemical combustion or nuclear fission as well as by other means such as the kinetic energy of flowing water and wind. There are many other technologies that can be and are used to generate electricity such as solar photovoltaics and geothermal power.

See also: Electricity Generation, Geothermal Energy, Hydrokinetic Energy, Ocean Energy, Solar Power, Wind Energy.

Electricity Generation – Equipment

Electric generators were known in simple forms from the discovery of electromagnetic induction in the 1830s. In general, some form of prime mover such as an engine or the turbines described above, drives a rotating magnetic field past stationary coils of wire thereby turning mechanical energy into electricity.

Almost all commercial electrical power on Earth is generated with a turbine, driven by wind, water, steam, or burning gas. The turbine drives a generator, thus transforming its mechanical energy into electrical energy by electromagnetic induction. There are many different methods of developing mechanical energy, including heat engines, hydropower, wind power, and tidal power.

Turbine types include: (i) steam in which water is boiled by fuel combustion, (ii) nuclear fission heat created in a nuclear reactor creates steam, (iii) renewable energy in which the steam is generated by biomass combustion, solar thermal energy, or geothermal energy, (iv) water energy which is captured by a water turbine from the movement of water such as from falling water, the rise and fall of tides or ocean thermal currents, (v) the windmill which is a form of the wind turbine.

See also: Turbine.

Electricity Generation from Conventional Fuels

Electricity generation is the process of generating electric power from sources of primary energy, such as fossil fuels. Electricity must be produced from other forms of energy in power plants (also called power stations). Electricity is most often generated at power plants by electromagnetic generators, primarily driven by heat engines fueled by combustion or nuclear fission but also by other means such as the kinetic energy of flowing water and wind. Other energy sources include solar photovoltaics and geothermal power.

The production of electric power by the combustion of coal, crude oil, or natural gas is a mature and well-established technology in the industrialized countries of the world, although other options are available. Put simply, power plants produce electricity by burning coal in a boiler to produce steam which, under high pressure, flows into a turbine, which spins a generator to create electricity. The steam is then cooled, condensed back into water, and returned to the boiler to start the process over. Thus:

Feedstock → boiler → turbine → generator → electricity → user

In the process of using a carbonaceous feedstock to generate electricity, the chemical energy of the feedstock is converted to thermal energy and the heat is used to generate high pressure steam that passes through a turbine to generate electricity. In a combined cycle, the feedstock is first combusted in a combustion turbine, using the heated exhaust gases to generate electricity. After these exhaust gases are recovered, they heat water in a boiler, creating steam to drive a second turbine. Apart from combustion, fossil fuels can also be gasified producing synthesis gas (syngas) – mixtures of carbon monoxide (CO) and hydrogen (H₂) – which can be directly used as a fuel for power generation. Alternatively, the hydrogen can be separated and used as a fuel in an open or combined cycle process.

The advent of stricter environmental controls on effluents from power plants, especially with respect to sulfur oxides, has required that new types of combustion/pollution control technology are emerging. In fact, the increased utilization of coal in place of oil and gas for combustion applications in the United States is motivating near-term development and implementation of alternative technologies for electricity generation from coal.

See also: Turbine.

Electricity Generation from Crops

In recent years, biofuels have become more attractive to many countries as possible replacements for fossil fuels. Therefore, understanding the sustainability of this renewable resource is important. There are many benefits associated with the use of biofuels such as reduced greenhouse gas emissions, lower cost than fossil fuels, and renewability, etc. These energy crops can be used to generate electricity. Wood cellulose and biofuel in conjunction with stationary electricity generation have been shown to be very efficient.

The projected increase in use/need of energy crops begs the question of whether this resource is sustainable. Increased biofuel production draws on issues relating to changes in land use, impacts on ecosystem (soil and water resources), and adds to competition of land space for use to grow energy crops, food, or feed crops. Plants best suited for future bioenergy feedstocks should be fast growing, high yielding, and require little energy input for growth and harvest. The use of energy crops for energy production can be beneficial because of its carbon neutrality and represents a cheaper alternative to fossil fuels while being extremely diverse in the species of plants that can be used for energy production. But issues regarding cost (more expensive than other renewable energy sources), efficiency, and

space required to maintain production need to be considered and improved upon to allow for the use of biofuels to be commonly adopted.

See also: Energy Crops, Electricity Generation from Conventional Fuels.

Electricity Generation from Waste

Waste-to-energy (WtE) or energy-from-waste (EfW) is the process of generating energy in the form of electricity and/or heat from the primary treatment of waste.

Incineration, the combustion of organic material such as waste with energy recovery, is the most common WtE implementation. Modern incinerators reduce the volume of the original waste by 95-96%, depending upon composition and degree of recovery of materials such as metals from the ash for recycling.

The method of incineration to convert municipal solid waste (MSW) is a relatively old method of WtE generation. Incineration generally entails burning waste (residual MSW, commercial, industrial, and RDF) to boil water which powers steam generators that generate electric energy and heat to be used in homes, businesses, institutions, and industries. One problem associated is the potential for pollutants to enter the atmosphere with the flue gases from the boiler. These pollutants can be acidic and in the 1980s were reported to cause environmental degradation by turning rain into acid rain. Modern incinerators incorporate carefully engineered primary and secondary burn chambers, and controlled burners designed to burn completely with the lowest possible emissions, eliminating, in some cases, the need for lime scrubbers and electro-static precipitators on smokestacks.

By passing the smoke through the basic lime scrubbers, any acids that might be in the smoke are neutralized which prevents the acid from reaching the atmosphere and hurting the environment. Many other devices, such as fabric filters, reactors, and catalysts destroy or capture other regulated pollutants.

See also: Combustion, Gas Cleaning, Gas Processing, Gas Treating.

Electricity Generation from Wood

Electricity generation from woody biomass has been growing steadily since 1990 with an approximate 2 to 3% average annual growth. As the second largest renewable electricity source after hydropower, solid biomass accounted for more than 5% of renewable electricity generation. Of the electricity generated from solid biomass, more than 40 TWh is accounted for by the USA. The second largest producer of electricity from solid biomass is Finland (>8 TWh).

Other big producers are Japan and Canada; in fact, electricity is produced from solid biomass in most Organisation for Economic Co-operation and Development (OECD) member countries. This mainly involves the combustion of commercial woody fuels in modern devices, for example, woodchip-fired co-generation plants for heat and power. Other applications are industrial heat supply and co-firing with coal for large-scale power generation.

See also: Energy From Crops, Energy From Wood.

Electricity Generator

An electricity generator (electric generator) is a machine that converts mechanical energy to electrical energy. The mechanical energy can be supplied by the prime mover such as (i) a combustion engine, (ii) a steam engine, (iii) water falling through turbine, or (iv) any such mechanism that can be a source of mechanical energy. Usually, this energy is obtained from a rotating shaft (also called the armature of the generator). The electric energy then produced can be used for power transmission to commercial, industrial, or even domestic level.

An electric generator is a device that converts mechanical energy obtained from an external source into electrical energy as the output. However, the generator does not actually create the electrical energy but uses the mechanical energy supplied to it to force the movement of electric charges present in the wire of its windings through an external electric circuit. This flow of electric charges constitutes the output electric current supplied by the generator.

The modern-day generator works on the principle of electromagnetic induction discovered by Michael Faraday in 1831-1832 who found that the flow of electric charges could be induced by moving an electrical conductor, such as a wire that contains electric charges, in a magnetic field. This movement creates a voltage difference between the two ends of the wire or electrical conductor, which in turn causes the electric charges to flow, thus generating electric current.

Currently, there are five major types of electric generators, classified according to the manner in which their field flux is produced which are (i) the separately excited generator, in which the field flux is derived from a separate power source independent of the generator itself, (ii) the shunt generator, in which the field flux is derived by connecting the field circuit directly across the terminals of the generator, (iii) the series generator, in which the field flux is produced by connecting the field circuit in series with the armature of the generator, (iv) the commutatively compound generator, in which both a shunt and a series field are present and their efforts are additive, and (v) the differentially compound generator, in which a differentially compounded generator, both a shunt and a series field are present, but their efforts are subtracted.

Currently, three basic types of power plants generate most of the electricity in the United States and are fossil fuel power plants, nuclear power plants, and hydropower power plants. There are also wind, geothermal, waste-to-energy, and solar power plants.

Fossil fuel plants burn coal, natural gas, or crude oil which use the chemical energy in fossil fuels to superheat water into steam, which drives a steam generator. Fossil fuel plants are sometimes called thermal power plants because they use heat to generate electricity. Nuclear plants generate electricity much as fossil fuel plants do, except that the furnace is a reactor and the fuel is typically uranium. In a nuclear plant, a reactor splits uranium atoms into smaller elements, producing a great amount of heat in the process. The heat is used to superheat water into high-pressure steam, which drives a turbine generator. Like fossil fuel plants, nuclear power plants are thermal plants because they use heat to generate electricity. Hydropower plants use the gravitational force of falling water to generate electricity which is the cheapest way to produce electricity in the United States, but there are places where new dams can be built economically. There are many existing dams that could be retrofitted with turbines and generators.

Electrochemical Processes

Electrochemical processes are widely used in the energy process industries, and the basic apparatus of an electrochemical process is the electrolytic cell which consists of an anode where oxidation reactions occur, a cathode where reduction reactions occur, an electrolyte which contains in ionic form the material to be converted, and a power supply to provide a direct current voltage between the electrodes. The cell may also contain one or more membranes between the electrodes which permit the passage of either cations or anions, but not both.

The processes are used frequently in the fuel industries for minimizing waste and converting toxic waste into more benign products as well as recycling process streams, nuclear decontamination, and wastewater treatment. Metals recovery can be achieved by electroplating the metal ions out of an aqueous waste stream since electrochemistry has the advantage that the metal can be recovered in its most valuable form – as the pure metal.

See also: Electrostatic Precipitator.

Electrolysis

Electrolysis is the process by which an electric current is passed through water and breaks the chemical bonds between hydrogen and oxygen. In the process, an electrolyte, a fluid chemical substance that can carry a current, aids in the bond-breaking procedure. Once the bonds are broken, the atomic components (hydrogen and oxygen) become either positive or negative ions (charged particles). Two terminals (anode and cathode) also have positive and negative charges, drawing the resulting ions toward them. Generally, the positive hydrogen ions gather at the anode (which is negative), while the negative oxygen ions reside at the cathode (which is positive). Gas is then formed at either terminal.

Water, being covalent, has very few ions in it, but the addition of a dilute acid or a salt such as sodium chloride provides sufficient ions to pass significant current. If sulfuric acid is used, as in the rechargeable battery of an automobile, the ions produced are H^+ and (SO_4^{2-}) . The positive hydrogen ions are attracted to the negative cathode, where they pick up an electron, normally combine to form a molecule, and are released as a free gas. The negative sulfate ions go to the positive anode, where they are neutralized, but then react with water to produce more sulfuric acid and release oxygen. The sulfuric acid acts as a catalyst, and the result is the splitting up of water into hydrogen and oxygen.

If an electrode such as titanium, tantalum, or palladium (which reacts exothermically with hydrogen) is used as the cathode, the metal becomes charged with hydrogen. Instead of being released as free gas, the hydrogen enters the metal and diffuses into the lattice. Hydride derivatives can form with concentrations of up to two hydrogen atoms per metal atom.

See also: Nuclear Fusion.

Electron

The electron is a subatomic particle (symbol e^-) that has a negative electric charge and has a mass that is approximately 1/1,836 that of the proton. The properties of the electron include a natural spin. Like all elementary particles, electrons exhibit properties of particles and waves and can collide with other particles and be diffracted.

Electrons play an essential role in numerous physical phenomena, such as electricity, magnetism, chemistry, thermal conductivity, and (most important in the current context) radioactivity, especially radioactive decay. Electrons radiate or absorb energy in the form of photons when they are accelerated.

Electrons can be created through beta decay of radioactive isotopes and in high-energy collisions. The antiparticle of the electron is the positron which is identical to the electron except that it carries electrical a positive charge. When an electron collides with a positron, both particles can cease to exist thereby producing gamma ray photons.

Electronic Waste

Electronic waste (e-waste or WEEE – waste electrical and electronic equipment) is a waste type consisting of any broken or unwanted electrical or electronic appliance. It is a point of concern considering that many components of such equipment are considered toxic and are not biodegradable.

Electronic waste includes computers, entertainment electronics, mobile phones, and other items that have been discarded by their original users. While there is no generally accepted definition of electronic waste, in most cases electronic waste consists of electronic products that were used for data processing, telecommunications, or entertainment in private households and businesses that are now considered obsolete, broken, or irreparable. Despite its common classification as a waste, disposed electronics are a considerable category of secondary resource due to their significant suitability for direct reuse (for example, many fully functional computers and components are discarded during upgrades), refurbishing, and material recycling of its constituent raw materials (listed below). The potential for electronic waste as a resource thus preempts its potentially hazardous qualities.

Electronic waste is a valuable source for secondary raw materials, if treated properly; however, if not treated properly, it is a major source of toxins. Rapid technology change, low initial cost, and even planned obsolescence have resulted in a fast-growing problem around the globe. Technical solutions are available, but in most cases, a legal framework, a collection system, logistics, and other services need to be implemented before a technical solution can be applied.

Electrostatic Precipitator

Electrostatic precipitation is the separation of liquid or solid particles from a gas stream by the action of electrically charged wires and plates. The precipitator is used for the collection of dusts, mists, and fumes which are defined by size or type, thus: (i) dust, which are solid particles from 0.1 to 100 microns (0.1 to 100) μm in diameter, (ii) mist, which is liquid droplets suspended in a gas, and (iii) fumes, which are solid or liquid particles formed by condensation from a vapor. The precipitator uses electrostatic forces which are induced by electrostatic charging of the solids and then dropping them under freefall between oppositely charged electrodes. The electrostatic field of the electrodes deflects the solids, depending on the charge, into separate receiving bins. A third is the ion exchange concept, which depends on the ability of molecules to ionize into positively charged and negatively charged ions which are removed from waste streams by replacing them with more desirable ions.

The basic components of a precipitator are the discharge (or corona) electrode, the collection electrode (plates), and the precipitator shell. Other components are the dust hopper, high-voltage equipment, and gas distributors. Suspended particles are charged by collisions with the negative ions passing through the zone between the corona and the collection electrode. Movement of the particles to the collection electrode is governed by the interaction of the electric field and charged particles in the moving gas stream.

The dust cake is then collected from the plate by striking it with rappers. The dust collection efficiency is a strong function of dust resistivity. In general, particles in a gas stream are charged by a high-voltage discharge electrode and collected at collection plates of opposite polarity. Particles of high resistivity create the most difficulty in collection. Because resistivity varies with temperature, this can be an important parameter. Conditioning agents such as sulfur trioxide have been used to lower resistivity. Other important parameters include design of electrodes, spacing of collection plates, minimization of air channeling, and collection-electrode rapping techniques (used to dislodge particles). Techniques under study include high-voltage pulse energization to enhance particle charging, electron-beam ionization, and wide plate spacing. Electrical precipitators are capable of high efficiencies >99% under optimum conditions, but performance is still difficult to predict in new situations.

The dust collection efficiency is a strong function of dust resistivity. In general, particles in a gas stream are charged by a high-voltage discharge electrode and collected at collection plates of opposite polarity. Particles of high resistivity create the most difficulty in collection. Because resistivity varies with temperature, this can be an important parameter. Conditioning agents such as sulfur trioxide have been used to lower resistivity. Other important parameters include design of electrodes, spacing of collection plates, minimization of air channeling, and collection-electrode rapping techniques (used to dislodge particles).

There are two main types of precipitators which are (i) high-voltage, single-stage precipitators which combine an ionization and a collection step which are commonly referred to as Cottrell precipitators and (ii) low-voltage, two-stage precipitators which use a similar principle; however, the ionizing section is followed by collection plates.

The majority of electrostatic precipitators installed are the plate type. Particles are collected on flat, parallel surfaces that are 8 to 12 in. (20 to 30 cm) apart, with a series of discharge electrodes spaced along the centerline of two adjacent plates. The contaminated gases pass through the passage between the plates, and the particles become charged and adhere to the collection plates. Collected particles are usually removed by rapping the plates and deposited in bins or hoppers at the base of the precipitator.

Tubular precipitators consist of cylindrical collection electrodes with discharge electrodes located on the axis of the cylinder. The contaminated gases flow around the discharge electrode and up through the inside of the cylinders. The charged particles are collected on the grounded walls of the cylinder. The collected dust is removed from the bottom of the cylinder. Tubular precipitators are often used for mist or fog collection or for adhesive, sticky, radioactive, or extremely toxic materials.

In the oil shale industry, electrostatic precipitators could be used in several operations, including mine ventilation and the second-stage cleaning of dust laden streams from crushers and conveyors.

Emissions and Effluents

Whatever the type of energy source (alternate or alternative, non-renewable or renewable) is used to produce fuels and energy, the capacity of the environment to absorb the effluents and other impacts of energy technologies is not unlimited, as some would have us believe. The environment should be considered to be an extremely limited resource, and discharge of chemicals into it should be subject to severe constraints. Indeed, the declining quality of many raw materials dictates that more material must be processed to provide the needed products. And the growing magnitude of the effluents from industrial processes has moved above the line where the environment has the capability to absorb such effluents without disruption. Thus, the general prognosis for environmental protection through an increased awareness of environmental issues is not pessimistic and can be looked upon as being quite optimistic.

In terms of gaseous emissions, the control of nitrogen oxides is achieved, to date, mainly through modification of the combustion process, and other methods, including various flue gas treating processes are being developed. Indeed, it is anticipated that flue gas control technologies may achieve significantly higher control of gaseous emissions than currently being recorded. In fact, the current flue gas desulfurization techniques are capable of removing approximately 90% w/w of the sulfur. However, it is extremely important that there is an understanding of the various types of emissions that escape to the atmosphere, as well as to the other constituents of the surrounding environment.

A number of inorganic emissions enter the atmosphere as the result of human activities. The most common of these emissions are sulfur dioxide (SO₂), nitric oxide (NO), and nitrogen dioxide (NO₂). Other inorganic gaseous emissions include ammonia (NH₃), hydrogen sulfide (H₂S), chlorine (Cl₂), hydrogen chloride (HCl), and hydrogen fluoride (HF), as well as other oxides of nitrogen. Because of carbon monoxide emissions from internal combustion engines, the highest levels of this gas tend to occur in congested urban areas at times specific times, such as during heavy road traffic periods (rush hours). Carbon monoxide emissions from automobiles may be lowered by employing a leaner air-fuel mixture, i.e., an air-fuel in which the weight ratio of air to fuel is relatively high. Current automobiles use catalytic exhaust reactors to cut down on carbon monoxide emissions and nitrogen oxide emissions. But, in more general terms, there is the need to increase the efficiency of automobile transportation (Nivola and Crandall, 1995) which, hopefully, would reduce the noxious emissions into the atmosphere.

If the carbon monoxide escapes to the atmosphere, it is generally agreed that it is removed from the atmosphere by reaction with hydroxyl radical:

This reaction is accompanied by other chemical reactions which lead to the regeneration of more hydroxyl radicals:

Soil microorganisms act to remove carbon monoxide from the atmosphere.

The sulfur cycle involves primarily hydrogen sulfide, sulfur dioxide, sulfur trioxide, and sulfates. Sulfur compounds enter the atmosphere to a large extent through human activities, primarily as sulfur dioxide from the combustion, or processing, of sulfur-containing fuels. Non-anthropogenic sulfur enters the atmosphere largely as hydrogen sulfide from volcanoes and from the biological decay of organic matter and reduction of sulfate.

Organic emissions may have a strong effect upon atmospheric quality. The effects of such emissions in the atmosphere may be divided into two major categories which are (i) direct effects, such as effects caused by exposure to the

emissions, and (ii) the formation of secondary pollutants, especially smog (a mixture of smoke and fog). Because of their widespread use in fuels, hydrocarbon derivatives predominate among organic atmospheric pollutants.

Crude oil products, primarily gasoline, are the source of most of the anthropogenic hydrocarbon emissions found in the atmosphere. The Clean Air Act of 1990 has already impacted the gasoline markets of the United States (Miller, 1994). Additives and reformulation have already been implemented in some case to meet regulations and emission standards required for compliance, and gasoline will continue to be reformulated.

Alkane derivatives are among the more stable hydrocarbon derivatives in the atmosphere. Because of their high vapor pressures, alkanes with 6 or fewer carbon atoms are normally present as gases; alkanes with 20 or more carbon atoms are present as aerosols or are adsorbed on to atmospheric particles. Alkanes with 6 to 21 carbon atoms per molecule may be present either as vapor or particles, depending upon conditions.

Alkenes enter the atmosphere from a variety of processes, including emissions from internal combustion engines and turbines, foundry operations, and crude oil refining. In addition to the direct release of alkenes, these hydrocarbon derivatives are commonly produced by the partial combustion and cracking (thermal decomposition) at high temperatures of alkanes, particularly in the internal combustion engine. Unlike alkanes, alkenes are highly reactive in the atmosphere, especially in the presence of nitrogen oxides, hydroxyl radicals, and sunlight. In addition, the reaction of molecular oxygen to the resulting radical results in the formation of the extremely reactive hydroperoxyl radical. These radicals then participate in chain reactions such as those involved in the formation of smog.

Single-ring aromatic compounds are important constituents of lead-free gasoline, which has largely replaced leaded gasoline. In fact, derivatives of naphthalene (which has two fused, conjugated, aromatic rings) and several compounds containing two or more unconjugated rings have been detected as atmospheric pollutants.

Polynuclear aromatic hydrocarbon derivatives (Table 2.4) are present as aerosols in the atmosphere because of their extremely low vapor pressure. The partial combustion of coal, which has an atomic hydrogen-to-carbon ratio close to or less than 1, is a source of polynuclear aromatic compounds which have considerable toxicity (Lee et al., 1981).

Carbonyl compounds, consisting of aldehyde derivatives ($RCHO$) and ketone derivatives (R^1COR^2 where R^1 and R^2 are the same or different hydrocarbon groups), enter the atmosphere from a large number of sources and processes. These include direct emissions from internal combustion engine exhausts, incinerator emissions, spray painting, polymer manufacture, printing, petrochemicals manufacture, and lacquer manufacture. Formaldehyde ($HCHO$) and acetaldehyde (CH_3CHO) are produced by microorganisms, and acetaldehyde is emitted by various types of vegetation.

As expected from their low vapor pressures, the lower-boiling organic halogen compounds are the most likely to be found in the atmosphere. The most abundant organic chlorine compounds in the atmosphere are methyl chloride (CH_3Cl) and carbon tetrachloride (CCl_4). Also found are methylene chloride (CH_2Cl_2), methyl bromide (CH_3Br), bromoform ($CHBr_3$), assorted chlorofluorocarbons and halogen-substituted ethylene compounds, such as trichloroethylene ($CHCl=CCl_2$), vinyl chloride ($CH_2=CHCl$), perchloroethylene ($CCl_2=CCl_2$), and ethylene dibromide (CH_2BrCH_2Br). Many of these types of chlorocarbon derivatives and chlorofluorocarbon derivatives have been implicated in the halogen-atom-catalyzed destruction of atmospheric ozone which filters out cancer-causing ultra-violet radiation from the sun.

Although inert in the lower atmosphere, chlorofluorocarbon derivatives undergo photodecomposition by the action of high-energy ultraviolet radiation in the stratosphere to release chlorine atoms which then react with ozone to produce chlorine monoxide.

While organic sulfur derivatives are not highly significant as atmospheric contaminants on a large scale, organic sulfur compounds can cause local pollution problems – not the least of which is the highly objectionable odor. Major sources of organic sulfur compounds in the atmosphere include microbial degradation, wood pulping, volatile matter evolved from plants, animal wastes, packing house and rendering plant wastes, starch manufacture, sewage treatment, and crude oil refining.

Aromatic amines are widely used as chemical intermediates, antioxidants, and curing agents in the manufacture of polymers (rubber and plastics), drugs, pesticides, dyes, pigments, and inks. A large number of heterocyclic nitrogen compounds have been reported in tobacco smoke, and it is inferred that many of these compounds can enter the atmosphere from burning vegetation. Coke ovens are another major source of these compounds. In addition to the derivatives of pyridine, some of the heterocyclic nitrogen compounds are derivatives of pyrrole.

Particulate matter is a term that has come to stand for (liquid or solid) particles in the atmosphere which may be organic or inorganic and originate from a wide variety of sources and processes. As one example, particulate matter is produced from mineral matter in a carbonaceous fuel that is converted during combustion to finely divided inorganic material referred to as fly ash. This low density ash can be carried out of the stack with the hot exhaust gases and also has the ability to adsorb polynuclear aromatic hydrocarbon derivatives. Furthermore, the practice of burning any finely divided carbonaceous fuel can contribute to fly ash emissions which are composed of several chemical species (such as arsenic, cadmium, mercury, thallium, and zinc compounds) that are of environmental significance in soil, in water, and in the atmosphere (Kothny, 1973). Indeed, the United States Clean Air Act of 1990 requires the evaluation of several trace elements with a view to the banning of such emissions.

The particulate matter (PM, also referred to as particulates, atmospheric aerosol particles, atmospheric particulate matter, or suspended particulate matter, SPM) is a collection of microscopic particles of solid particles (or even liquid matter) suspended in the air. The term aerosol commonly refers to the particulate/air mixture, as opposed to the particulate matter alone. The source of the particulate matter can be natural or anthropogenic. The particulate matter can have impacts on climate and precipitation that adversely affect human health in ways additional to direct inhalation. The particulate matter is often categorized by size of the particles such as (i) coarse particles, which are designated PM_{10} with a diameter of 10 micrometers (10 microns, 10 μm ; (1 micron = 1 meter $\times 10^{-6}$) or less, (ii) fine particles, designated $PM_{2.5}$ with a diameter of 2.5 μm or less, (iii) ultrafine particles, $PM_{0.1}$, and (iv) soot. All of the aforementioned particles are inhalable to congregate in the lungs and, therefore, are a hazard to human health.

Soot as an airborne contaminant in the environment has many different sources, all of which are results of thermal decomposition, particularly pyrolysis. The sources include soot from coal combustion, internal-combustion engines, power-plant boilers as well as a variety of boilers, waste incineration local field (agricultural) burning, house fires, forest fires, fireplaces, and furnaces. These exterior sources also contribute to the indoor environment sources such as smoking of plant matter, cooking, oil lamps, candles, quartz/halogen bulbs with settled dust, and defective furnaces.

The formation of soot depends strongly on the fuel composition. The rank ordering of the soot forming tendency (also referred to as the propensity for soot formation) of fuel components is:

Naphthalene derivatives > benzene derivatives > aliphatic derivatives

However, the order of the soot-forming propensity within any of the above chemical hydrocarbon groups varies dramatically and is dependent on the structural type of the hydrocarbon derivative and the heteroatom (N, O, S) content.

Thus, particulate matter, which ranges in size from approximately one-half millimeter down to molecular dimensions, may consist of either solids or liquid droplets. Atmospheric aerosols are solid or liquid particles smaller than 100 microns in diameter. Pollutant particles in the 0.001 to 10 micron range are commonly suspended in the air near sources of pollution, such as the urban atmosphere, industrial plants, highways, and power plants. The small, solid particles include carbon black, silver iodide (AgI), combustion nuclei, and sea-salt nuclei, and the larger particles include cement dust, windblown soil dust, foundry dust, and any pulverized solid fuel – thus, the need for dust control is strong (Mody and Jakhete, 1988). On the other hand, the liquid particulate matter (mist) includes raindrops,

fog, and sulfuric acid mist and some particles are of biological origin, such as viruses, bacteria, bacterial spores, fungal spores, and pollen. Atmospheric particles undergo a number of processes in the atmosphere. Sedimentation and scavenging by raindrops and other forms of precipitation are the major mechanisms for particle removal from the atmosphere; particulate matter also reacts with atmospheric gases.

Dispersion aerosols, such as dusts, formed from the disintegration of larger particles are usually above 1 micron in size. Typical processes for forming dispersion aerosols include evolution of dust from coal grinding, formation of spray in cooling towers, and blowing of dirt from dry soil. Many dispersion aerosols originate from natural sources, such as sea spray, windblown dust, and volcanic dust. However, a vast variety of human activities break up material and disperse it to the atmosphere.

Metal oxides constitute a major class of inorganic particles in the atmosphere. These are formed during the combustion of fuels that containing metals. For example, particulate iron oxide is formed during the combustion of pyrite-containing coal:

Organic vanadium in residual fuel oil is converted to particulate vanadium oxide. Part of the calcium carbonate in the ash fraction of coal is converted by heat to calcium oxide and is emitted to the atmosphere through the stack:

A common process for the formation of aerosol mists involves the oxidation of atmospheric sulfur dioxide to sulfuric acid, a hygroscopic substance that accumulates atmospheric water to form small liquid droplets:

In the presence of basic air pollutants, such as ammonia (NH_3) or calcium oxide (CaO), the sulfuric acid (H_2SO_4) reacts to form the ammonium or calcium salts. Under conditions of low humidity, water is lost from these droplets and a solid aerosol is formed.

A significant portion of organic particulate matter is produced by internal combustion engines. These products may include nitrogen-containing compounds and oxidized hydrocarbon polymers. Lubricating oil and its additives may also contribute to organic particulate matter.

Particulate carbon as soot, carbon black, coke, and graphite originates from auto and truck exhausts, heating furnaces, incinerators, power plants, and steel and foundry operations and composes one of the more visible and troublesome particulate air pollutants. Because of its good adsorbent properties, carbon can be a carrier of gaseous and other particulate pollutants. Particulate carbon surfaces may catalyze some heterogeneous atmospheric reactions, including the important conversion of sulfur dioxide to sulfate.

Another mineral worthy of note as a pollutant is asbestos which is of considerable concern as an air pollutant because when inhaled, the fibrils can lodge in human tissue and cause asbestosis (a pneumonia condition), mesothelioma (tumor of the mesothelial tissue lining the chest cavity adjacent to the lungs), and bronchogenic carcinomas (cancer originating with the air passages in the lungs).

By way of definition, asbestos is the name given to a group of six fibrous silicate minerals, typically those of the serpentine group. Chemically, asbestos is a group of impure magnesium silicate minerals and colors may be white, gray, green, or brown, and is noncombustible. Serpentine asbestos is the mineral chrysotile, a magnesium silicate with strong and flexible fibers. Spinning is possible with the longer fibers. Amphibole asbestos includes various silicates of magnesium, iron, calcium, and sodium. The fibers are generally brittle and cannot be spun, but are more resistant to chemicals and to heat than serpentine asbestos. Because asbestos has long been indicated in asbestosis (similar to silicosis) and, in more recent years, considered a carcinogen, several countries have issued regulations that restrict its use. For many years, it has been used in fireproof fabrics, brake lining, gaskets, roofing, insulation, paint fillers, reinforcing agents in rubber and plastics, and in electrolytic diaphragm cells.

As a side note, talc is a clay mineral that is composed of hydrated magnesium silicate $[\text{Mg}_3\text{Si}_4\text{O}_{10}(\text{OH})_2]$ and has been known to occur with asbestos.

Some of the metals found predominantly as particulate matter in polluted atmospheres are known to be hazardous to human health. All of these except beryllium are so-called heavy metals. Lead is the toxic metal of greatest concern in the urban atmosphere because it comes closest to being present at a toxic level; mercury ranks second. Others include beryllium, cadmium, chromium, vanadium, nickel, and arsenic (a metalloid). Arsenic can have a significant effect on the environment, whether the metalloid is released to the land, the water, or the air (Nriagu, 1994a 1994b).

Atmospheric mercury (Hg^0) is of concern because of its toxicity, volatility, and mobility. Some atmospheric mercury is associated with particulate matter. One means by which mercury can enter the atmosphere is as volatile elemental mercury from coal combustion (ASTM D3684). Volatile organic mercury compounds such as dimethyl mercury $[(\text{CH}_3)_2\text{Hg}]$ and methyl mercury salts, such as methyl mercury bromide (CH_3HgBr) , are also encountered in the atmosphere. With the reduction in the use of leaded fuels, atmospheric lead is of less concern than it used to be.

A significant natural source of radionuclides in the atmosphere is radon, a noble gas product of radium decay. Radon may enter the atmosphere as either of two isotopes, ^{222}Rn (half-life: 3.8 days) and ^{220}Rn (half-life: 54.5 seconds). Both are alpha emitters in decay chains that produce a series of daughter products and terminate with stable isotopes of lead. The initial decay products, isotopes of polonium (^{218}Po and ^{216}Po), are nongaseous and adhere readily to atmospheric particulate matter. Therefore, some of the radioactivity detected in these particles is of natural origin.

One of the more serious problems in connection with radon is that of radioactivity originating from uranium mine tailings that have been used in some areas as backfill, soil conditioner, and a base for building foundations. Radon produced by the decay of radium exudes from foundations and walls constructed on tailings. Some medical authorities have suggested that the rate of birth defects and infant cancer in areas where uranium mill tailings have been used in residential construction are significantly higher than normal.

The combustion of fossil fuels introduces radioactivity into the atmosphere in the form of radionuclides contained in fly ash. Large coal-fired power plants lacking ash-control equipment may introduce up to several hundred millicuries of radionuclides into the atmosphere each year, far more than either an equivalent nuclear or an equivalent oil-fired power plant.

The radioactive noble gas krypton (^{85}Kr) has a half-life on the order of 10.3 years and is emitted into the atmosphere by the operation of nuclear reactors and the processing of spent reactor fuels. In general, other radionuclides produced by reactor operation are either chemically reactive and can be removed from the reactor effluent or have such short half-lives that a short time delay prior to emission prevents them from leaving the reactor.

The above-ground detonation of nuclear weapons can add large amounts of radioactive particulate matter to the atmosphere. Although there are general agreements between several nations to cease and desist from testing nuclear devices in the atmosphere, not all nations agree to this proposition.

It is considered likely that most of the environmental impact of mineral resource development (including the hazards of coal mining, gaseous emissions, and acid precipitation) could be substantially abated. A considerable investment in retrofitting or replacing existing facilities and equipment might be needed. However, replacing coal with natural gas, which releases less carbon dioxide per unit of energy, is at best a short-term solution.

Minimizing the carbon dioxide emissions from many mineral resources (which must also include emissions of hydrogen sulfide) would require revamping of the current technology. But it is possible, and a conscious goal must be to improve the efficiency with which the resources are transformed and consumed and by shifting to alternative products.

In terms of the production of transportation fuels from biomass sources, ethanol (ethyl alcohol; grain alcohol) is a major biomass fuel, but in the current market conditions, it remains significantly more expensive than gasoline. The widespread use of biomass (alcohol) fuel is constrained by the size of the resource base from which they are produced. There is also the argument that methyl alcohol (methanol) produced from natural gas releases as much carbon dioxide as does gasoline. The counterargument is that methanol-fueled engines have a greater potential for improvements than gasoline engines do (for example, they can function at higher levels of compression than have heretofore been attempted).

There is the need for the systematic identification and evaluation of the potential impacts of proposed projects, plans, programs, policies, or legislative actions upon the physical-chemical, biological, cultural, and socioeconomic

components of the environment. Also known as environmental impact assessment, it also includes the consideration of measures to mitigate undesirable impacts. The primary purpose of environmental impact assessment is to encourage consideration of the environment in planning and decision making and ultimately to arrive at actions that are environmentally compatible.

Impact assessment refers to the interpretation of the significance of anticipated changes related to the proposed project. Impact interpretation can be based upon the systematic application of the definition of significance, as described earlier. For some types of anticipated impacts, there are specific numerical standards or criteria that can be used as a basis for impact interpretation. Examples include airquality standards, environmental noise criteria, surface-water and groundwater quality standards, and wastewater discharge standards for particular facilities. The latter is especially true since the quality of wastewater can vary with the nature of the facility.

In this context, it is necessary to consider the impacts related to the biological environment and the potential significance of the loss of particular habitats, including wetland areas (Dennison and Berry, 1993). Another basis for assessment is public input, which could be received through the scoping process or through public participation programs.

Identifying and evaluating potential impact mitigation measures should also be an activity in the process of environmental impact assessment. Mitigation can be defined as the sequential consideration of measures such as (i) avoiding the impact by not taking a certain action or parts of an action, (ii) minimizing impacts by limiting the degree or magnitude of the action and its implementation, (iii) rectifying the impact by repairing, rehabilitating, or restoring the affected environment, (iv) reducing or eliminating the impact over time by preservation and maintenance operations during the life of the action, and (v) compensating for the impact by replacing or providing substitute resources or environments. Examples of mitigation measures include pipeline routing to avoid archeological resources, inclusion of pollution-control equipment on airborne and liquid discharges, reductions in project size, revegetation programs, wildlife protection plans, erosion control measures, remediation activities, and creation of artificial wetlands.

A key activity in environmental impact assessment is associated with selecting the proposed action from alternatives that have been evaluated (Inhaber, 1982). In public projects, there is considerable emphasis on the evaluation of alternatives; in fact, various regulations (Majumdar, 1993) indicate that the analysis of alternatives represents the heart of the impact assessment process. Conversely, for many private developments, the range of alternatives may be limited. Even so, there are still potential alternative measures that could be evaluated, including those relating to project size and design features even if location alternatives are not available.

Environmental impact studies need to address a minimum of two alternatives, and can include more than fifty alternatives. Typical studies address three to five alternatives. The minimum number usually represents a choice between the construction and operation of a project versus project rejection. The alternatives may encompass a wide range of alternate considerations such as (i) site location, (ii) design of a site, (iii) construction, operation, and decommissioning options, (iv) project size, (v) phasing in of operational units, (vi) timing of the construction, operation, and decommissioning activities, and (vii) the option that related to a non-project.

All of the aforementioned arguments for and against the use of resources do not belie the obvious. Mineral resources, including fossil fuel resources, will continue to be sources of valuable products for the next several decades. They must be used judiciously insofar as they are sources of pollutants, many of which are gases and which must not be released to the atmosphere.

Obviously, much work is needed to accommodate the change to a different fuel source. In the meantime, there must be serious efforts to improve efficient usage and working to ensure that there is no damage to the environment. Such is the nature of resource development and use and the expectancy of environmental protection.

Emission Control

Emission control by direct flame incineration systems (thermal combustion) is widely used to reduce the amounts of hydrocarbon vapors, aerosols, and particulate in gas streams. These systems are also used to remove odors and reduce the opacity of plumes from ovens, dryers, stills, cookers, and refuse burners.

The operation consists of ducting the process exhaust gases to a combustion chamber where direct-fired burners burn the gases to their respective oxides. Catalytic incineration is also used for the same purpose. The chief difference is that the combustion chamber is filled with a catalyst. On contact with the catalyst, certain components of the process gases are oxidized.

The use of a catalyst allows more complete combustion at lower temperatures, thus reducing fuel consumption and allowing the use of less expensive furnace construction. However, catalysts are generally selective and may not destroy as many contaminants as direct flame incineration. In addition, because of the potential for catalyst fouling and poisoning, gas streams may need to be cleaned of smoke, particulate, heavy metals, and other catalyst poisons. Condensation is usually combined with other air pollution control systems to reduce the total pollutant load on more expensive control equipment. When used alone, condensation often requires costly refrigeration to achieve the low temperatures needed for adequate control.

Several methods can be used for cooling the gas streams. In surface condensers, the coolant does not contact the vapor or condensate; condensation occurs on a wall separating the coolant and the vapor. Most surface condensers are common shell-and-tube heat exchangers. The coolant normally flows through the tubes; the vapor condenses on the cool outside tube surface as a film and is drained away to storage or disposal.

Contact condensers usually cool the vapor by spraying a liquid, at ambient temperature or slightly cooler, directly into the gas stream. They also act as scrubbers in removing vapors that do not normally condense. The use of quench water as the cooling medium results in a waste stream that must be contained and treated before discharge.

The equipment used for contact condensation includes simple spray towers, high-velocity jets, and barometric condensers. Contact condensers are, in general, less expensive, more flexible, and more efficient in removing organic vapors than surface condensers. On the other hand, surface condensers recover marketable condensate and present no waste disposal problem. Surface condensers require more auxiliary equipment and need more maintenance.

Condensers have been widely used (usually with additional equipment) in controlling organic emissions from crude oil refining, petrochemical manufacturing, dry cleaning, decreasing, and tar dipping. Refrigerated condensation processes are being used for the recovery of gasoline vapors at bulk terminals and service stations.

Emulsification

An emulsion is a mixture of two or more liquids that are usually immiscible. Examples include crude oil and water which can form an oil-in-water emulsion, wherein the oil is the dispersed phase, and water is the dispersion medium or a water-in-oil emulsion, wherein the water is the dispersed phase, and the oil is the dispersion medium. The physical structure of an emulsion is based on the size of the droplets – most emulsions contain droplets with a mean diameter of more than approximately 1 μm (1 micron, 1×10^{-6} meter); however, mini-emulsions and nano-emulsions can be formed with droplet sizes in the 100 to 500 nm (nanometer, 1×10^{-9} meter) range, and with proper formulation, highly stable microemulsion can be prepared having droplets as small as a few nanometers.

When the water and an organic liquid (such as bio-oil) are combined by emulsification, two emulsion structures are possible. The oil phase may become dispersed throughout the aqueous phase to produce an oil-in-water (o/w) emulsion. Alternatively, the aqueous phase may become dispersed throughout the oil phase to produce a water-in-oil (w/o) emulsion. In general, an emulsion tends to exhibit the characteristics of the external phase. Two emulsions of similar composition can have different properties, depending on their structure. For example, an o/w emulsion can be diluted with water, colored with water-soluble dye and has a relatively high electrical conductivity compared to a w/o system. The latter is best diluted with oil and colored with oil-soluble dye. Many factors can influence the type of emulsion formed when two phases are mixed, including the type of emulsifying agent used, the relative proportions of the phases, and the method of preparation employed.

Emulsions with more complex structures, known as *multiple emulsions*, may also be produced. These may have oil-in-water-in-oil (o/w/o) or water-in-oil-in-water (w/o/w) structures. The latter structure has the most applications. w/o/w emulsions may be produced in two stages. First, a w/o emulsion is produced by homogenization using a hydrophobic agent. This is then incorporated into an aqueous phase using a hydrophilic agent. In such a multiple emulsion, the oil layer is thin and water can permeate through it due to an osmotic pressure gradient between the

two aqueous phases. This property is used in certain applications including prolonged drug delivery systems, drug overdose treatments, and nutrient administration for special dietary purposes.

In a two-phase system, free energy exists at the interface between the two immiscible liquids, due to an imbalance in the cohesive forces of the two materials. Because of the interfacial tension, there is a tendency for the interface to contract. Thus, if a crude emulsion is formed by mixing two immiscible liquids, the internal phase will take the form of spherical droplets, representing the smallest surface area per unit volume. If the mixing is stopped, the droplets coalesce to form larger ones and eventually, the two phases will completely separate. To form an emulsion, this interfacial tension has to be overcome. Thus, energy must be introduced into the system. This is normally achieved by agitating the liquids. The greater the interfacial tension between the two liquids, the more energy required to disperse the internal phase. Reducing this interfacial tension will facilitate the formation of an emulsion. This is one important role of emulsifying agents. Another function of these agents is to form a protective coating around the droplets of the internal phase and thus prevent them from coalescing and destabilizing the emulsion.

The stability of an emulsion refers to the ability of the emulsion to resist change in form and properties over time. There are three types of instability in emulsions: (i) flocculation, (ii) creaming, and (iii) coalescence. Flocculation occurs when there is an attractive force between the droplets, so they form a flocculant mass (flocs) in the fluid through precipitation or aggregation of suspended particles. Creaming occurs when the droplets rise to the top of the emulsion under the influence of buoyancy. Coalescence occurs when droplets collide and combine to form a larger droplet, so the average droplet size increases over time. Use of a surface-active agent (surfactant) can increase the stability of an emulsion so that the size of the droplets does not change significantly with time and the emulsion is then defined as a *stable emulsion*.

This demulsification process can be slowed with the help of emulsifiers which are surface-active substances with strong hydrophilic properties that are used to eliminate the prolonged effects of spills in which emulsions are formed. Emulsifiers help to stabilize emulsions and promote dispersing the phase oil to form microscopic (invisible) droplets which may accelerate the decomposition of the pollutant in the water.

The formation of an emulsion based on water and chemicals is less likely than in the case of water and organic chemicals. Nevertheless, the properties of chemicals as a function of the solubility in water is important because of the potential use of the chemicals to break, for example, an o/w emulsion that forms after a crude oil spill into the aquasphere and the potential to aid in the clean-up process.

See also: Water.

Emulsifying Agents

Emulsifying agents are chemicals with good emulsifying properties and have molecular structures which contain both polar and nonpolar groups. Polar groups have an affinity for water, i.e., are hydrophilic, while nonpolar groups are hydrophobic. If there is a small imbalance between the polar and nonpolar groups in the molecules of a substance, it will be adsorbed at the interface between the phases of an emulsion. These molecules will become aligned at the interface so that the polar groups will point toward the water phase, while the nonpolar groups will point toward the oil phase. By bridging the interface in this way, they reduce the interfacial tension between the phases and form a film around the droplets of the internal phase, thus stabilizing them. A substance in which the polar group is stronger will be more soluble in water than one in which the nonpolar group predominates. Such a substance will tend to promote the formation of an o/w emulsion. However, if the nonpolar group is dominant, the substance will tend to produce a w/o emulsion. If the polar and nonpolar groups are grossly out of balance, the substance will be highly soluble in one or other of the phases and will not accumulate at the interface. Such materials do not make good emulsifying agents.

The emulsifying capability of an agent may be classified according to the hydrophile-lipophile balance (HLB) in its molecules. This is defined as the ratio of the weight percentage of hydrophilic groups to the weight percentage of hydrophobic groups in the molecule. Hydrophile-lipophile balance values for emulsifying agents range from 1 to 20. Agents with low values, 3 to 6, promote the formation of w/o emulsions, while those with high values, 8 to 16, favor the formation of o/w types. Agents with even higher hydrophile-lipophile balance values are used in detergents and solubilizers.

Protein, phospholipids, and sterols, which occur naturally in many types of biomass, act as emulsifying agents. A wide range of manufactured agents is available, both ionic and nonionic. Ionic emulsifiers often react with other oppositely charged particles such as hydrogen and metallic ions to form complexes. This may result in a reduction in solubility and emulsifying capacity. Hydrocolloids such as pectin and gums are often used to increase the viscosity of emulsions to reduce separation of the phases under gravity (creaming).

See also: Emulsification.

Endothermic Reaction

An endothermic reaction is a process in which heat is absorbed. The heat has to be supplied to the system from the surroundings. This heat is transferred to the surroundings. A thermo-neutral reaction process is one that neither requires heat from the surroundings nor gives off energy to the surroundings.

These terms are usually applied to chemical reactions. A chemical reaction can only be one of these three terms at once. A reaction that is exothermic will be endothermic if run backward and vice-versa.

In a chemical reaction, reactants are converted into products by the breaking and making of chemical bonds. Bond breaking requires energy, while bond making releases energy. The balance between the two gives a positive or negative energy change for the reaction, and chemical reactions are classed as being either *endothermic*, with a positive energy change, or *exothermic*, with a negative energy change.

In an endothermic reaction, more energy is taken breaking bonds than is released making them, so the reaction proceeds with a net absorption of energy. In an exothermic reaction, the reverse is true and energy is released.

Thus, an endothermic reaction is a process in which energy (heat, light) is absorbed or requires heat input into the system (Figure E-1). The heat has to be supplied to the system from the surroundings or from a heat source.

Figure E-1 Representation of an endothermic reaction in which the heat content of the products is greater than the heat content of the reactants.

A *thermoneutral* reaction process is one that neither requires heat from the surroundings nor gives off energy to the surroundings.

Endothermic reactions are in the minority, and most chemical reactions release energy. Although an endothermic reaction usually needs energy to initiate the reaction, some endothermic reactions occur without initiation. Compounds formed by endothermic reactions have stored or potential chemical energy in their bonds, which may be released spontaneously in an explosion, such as in the case with chlorates, perchlorates, and nitrates.

See also: Exothermic Reaction.

Energy

Energy (from whatever the sources – fossil fuel sources or alternate sources) appears in many different forms, including electricity, light, heat, chemical energy, and motional (or kinetic) energy. An important scientific

discovery in the 19th century was that energy is conserved which means that energy can be converted from one form to another but that the total amount of energy must stay the same. Mass is also familiar, though sometimes it is referred to, rather inaccurately, as weight. On the surface of the Earth, mass and weight are often thought of as being the same thing, and they do use the same units – something that weighs 1 kilogram has a mass of 1 kilogram – but in reality, weight is the force that a mass experiences in the gravity of the Earth. An object always has the same mass, even though in outer space, it might appear to be weightless. Mass, like energy, is conserved.

Energy Balance

The energy balance is the difference between the energy produced by a fuel and the energy required to obtain it through agricultural processes, drilling, refining, and transportation.

All biomass goes through at least some of these steps: it needs to be grown, collected, dried, fermented, and burned. All of these steps require resources and an infrastructure. The total amount of energy input into the process compared to the energy released by burning the resulting ethanol fuel is known as the energy balance (net energy gain).

Energy balance estimates are not easily produced; thus numerous such reports have been generated that are contradictory. For instance, the production of ethanol from sugarcane, which requires a tropical climate to grow productively, returns from 8 to 9 units of energy for each unit expended, as compared to corn which only returns approximately about 1 to 2 units of fuel energy for each unit of energy expended. As a positive example, biodiesel (depending upon the production train) has a positive energy balance: for energy unit of energy required to produce biodiesel, 2.5 to 3.2 units of energy are gained. In addition, carbon dioxide, a greenhouse gas, is emitted during fermentation and combustion. However, this is canceled out by the greater uptake of carbon dioxide by the plants as they grow to produce the biomass. When compared to gasoline, depending on the production method, ethanol releases less greenhouse gases.

See also: Energy Content, Ethanol, Fossil Fuels.

Energy Conservation

Energy is a primary input to development. Fossil and nuclear fuels are fast depleting in different countries. Energy conservation is the decision and practice of using less energy. Turning off the light when leaving the room, unplugging appliances when they are not in use, and walking instead of driving are all examples of energy conservation. The two main reasons people conserve energy are to gain more control over the demand on the Earth's natural resources. Energy conservation is an important part of the transition to clean, renewable energy. By promoting initiatives to encourage and assist the community to adopt less energy-intensive lifestyles, the shift to 100% renewable energy can be an easier transition and the environmental impact can be reduced.

Energy conservation is the first step to a sustainable future because of the low risk and high reward. If there is a movement to decrease energy demand through energy conservation, reliance on nonrenewable energy sources can be reduced while at the same time expanding proliferation of renewable energy. Energy conservation is only part of the solution, especially in a growing economy. Energy conservation focuses on changing human behavior to utilize energy in a more efficient manner. Energy conservation behavioral changes can be made for little or no cost. Sustainable energy is the peak of the pyramid and so must be the last part of the pyramid to be built.

Energy conservation appears to be one of the most effective methods to increase and use energy efficiency, and to decrease energy consumption and greenhouse gas (GHG) emissions in various sectors. Therefore, many countries have recently started improving enterprising energy conservation programs to decrease the energy intensity of the country's infrastructure.

Energy conservation is now an important social topic. There is an expanding body of knowledge in the literature focused on promoting consumers in decreasing their personal carbon footprint in their domestic context. However, most of the research in the workplace focuses on optimizing formalized production processes and investing in energy-efficient equipment.

In sustainable development, energy resources create little or no wastes to be emitted into the environment and they cause only waste emissions having no or minimal negative impact on the environment. However, all resource use leads to some degree of environmental problem, and limitations imposed on sustainable development by environmental emissions can be in part overcome through increased efficiency. A large number of potential solutions to environmental problems related to the harmful pollutant emissions have been worked out, recently. A significant one among them is energy conservation. Energy conservation activities have been improved because of its indirect contribution to the prevention of environmental pollution.

Energy conservation is commonly listed as the main method of response. Governments should improve and apply energy conservation policies to decrease the impacts of environmental problem. The creation of any energy conservation policy could lead to a reduction in economic growth and eventually to a fall in income and employment.

Energy Content

Thermal energy is released from organic materials as the carbohydrates and other hydrocarbon derivatives (lignin and volatile chemicals) are ultimately reduced to carbon dioxide and water. The amount of usable thermal energy that can be obtained from fuel is known as the higher heating value (HHV). By contrast, the lower heating value (LHV) is equivalent to the HHV of the fuel minus heat required to vaporize the liquid water of the fuel. Interestingly, on a dry, ash-free basis, most biomass has approximately the same energy content (HHV) of 8,000 to 8,500 British thermal units per pound (Btu/lb). However, the practical heating value of biomass, as received, varies considerably due to differences in the content of ash-forming minerals and moisture.

Chemical composition, and therefore heat content, varies by plant component and biomass type. For example, the relative proportions of carbohydrates and other hydrocarbon derivatives vary between the two types of woody biomass: softwoods and hardwoods. Carbohydrates carry a lower heat content (6,000 to 7,000 Btu/lb) than the other hydrocarbon derivatives in organic matter (such as lignin at 10,000 to 12,000 Btu/lb) but are easier to hydrolyze into higher-value fuels and chemicals in fermentation processes than other hydrocarbon derivatives. Softwoods generally contain a higher percentage of volatile hydrocarbon derivatives, in the form of gums and resins, than do hardwoods. As a result, softwoods often, but not always, have higher heat content than hardwoods. In addition, bark often has higher lignin content than wood, which is one reason why its HHV is higher than wood of the same species.

Fuels with low heat content increase feedstock transportation costs per unit of usable thermal energy, thereby affecting the economics of biomass power generation. While it may be possible to pay less per ton for a feedstock with a lower HHV, it is likely to cost the same amount to transport a ton of low-energy fuel as it would to transport a ton of high energy-density material.

In addition, the energy content of biomass fuels per unit volume can increase feedstock quantity requirements for combustion and gasification. This affects storage, handling, and processing needs and the sizing of boiler and gasification systems. For example, using biomass fuels with low energy densities per unit volume may require a larger boiler vessel to achieve the same heat output as a boiler system run with a biomass fuel that has a higher energy density.

Energy Crops

Energy crops are agricultural crops grown specifically for their energy value (fuel value) (Table E-2) and include food crops such as corn and sugarcane, and nonfood crops such as poplar trees and switchgrass.

Table E-2 Examples of the properties of straw and energy crops.

Property	Cereal straw	Energy crops
Proximate analysis		
Ash, % w/w	3-10	6.2-7.5
Moisture, % w/w	14-25	15-20
Volatile matter, % w/w w/	70-81	>70
Ash melting point, oC	700-1,000	700-1,200
Elemental analysis		
C, % w/w	45-48	45.5-46.1
H, % w/w	5.0-6.0	5.7-5.8
N, % w/w	0.4-0.6	0.50-1.0
O, % w/w	36-48	41-44
S, % w/w	0.05-0.2	0.08-0.13
Cl, % w/w	0.14-0.97	0.09
K, % w/w	0.69-1.3	0.3-0.5
Ca, % w/w	0.1-0.6	9

Energy crops such as grasses, miscanthus oilseed crops, short rotation woody crops, residual herbaceous biomass, starch crops, sugar crops, and switchgrass can be converted to liquid biofuels by thermochemical and biochemical conversion process. The most appropriate biomass crop for energy production is one that can be harvested dry and has a perennial growth habit (no need for annual planting or tillage) to minimize cultivation costs. Low input of fertilizers and other chemicals when growing these plants helps to improve the energy efficiency. It is also important that plants can convert solar energy efficiently. Two major pathways of photosynthesis are the C3 and C4 pathway. In general, the C3 assimilation path is adapted to operate under low temperature (15-20°C) whereas in the C4 metabolic pathway, species are more efficient converters in high light level and high temperature situations. Tropical grasses, such as sugar cane, maize, also miscanthus and sweet sorghum are C4 plants.

C4 plants can generate a theoretical maximum dry matter yield of 22 tons per acre in a year compared with 13 tons per acre from normal C3 temperate crops. However, C4 plants can only generate such a yield under hot climate conditions. In temperate climate, C3 plants might be more suitable. For example, short rotation forestry suitable for energy production under temperate climate is generally the C3 species – such as willow and poplar.

In order to determine suitability of energy crops to grow them in a chosen area, the following factors should be considered: the energy balance, agronomic factors such as crop yields, soils and climate, energy output per hectare, and effective utilization of all of the components of the crop at the processing stage. Calorific value, amount of ash the plants produce when used, as well as their moisture content are of a crucial importance for energy production.

Generally, the C4 crops such as Miscanthus are more suitable for arable lands whereas C3 crops can be grown on marginal land. In order to make the crop growing process environmentally friendly, a transportation distance should be as short as possible and should not exceed 40 km.

Markets for biomass crops have been slow to develop. The concept of co-firing biomass in existing power plants continues to show promise. Electric utilities are interested in co-firing biomass as a way to meet the renewable energy mandate, should it become law. In addition, there are air quality benefits from biomass fuels. Since biomass fuels are low in sulfur and nitrogen – SO_x which causes acid rain and NO_x which contributes to smog is lower in smokestack emissions when biomass fuels are burned with coal.

There are many opportunities for producing fuel from agricultural crops and crop residues. Possible end products include ethanol, vegetable oil, and solid cellulosic fuels. Ethanol can be produced from any grain, root, fruit, or juice crop containing fermentable carbohydrates. It also can be made from crops, residues, or wood that contain cellulose or other long-chain carbohydrates which can be hydrolyzed to fermentable sugars.

Vegetable oils are produced from numerous oil seed crops. Some of these oils have been evaluated in other laboratories as substitutes for diesel fuel. While all vegetable oils have high energy content, most require some processing to assure safe use in internal combustion engines.

The simplest form of agricultural biomass energy use involves direct combustion of cellulosic crops or residues, such as hay, straw, or corn fodder, to heat space or produce steam. Such fuels are useful for heating farm buildings and small commercial buildings in rural areas and for drying crops. Ideally, energy crops should be produced on land not needed for food production. This use should not increase the erosion hazard or cause other environmental damage.

On the other hand, a variety of crops can be grown specifically to provide sources of energy, and once established, a stand of perennial biomass/energy crop is expected to remain productive for a period of 6 years or more.

Thus, perennial crops that regenerate annually from buds at the base of the plant offer the greatest potential for energy-efficient production. These include (i) short rotation coppice, (ii) miscanthus, (iii) reed canary grass, (iv) cordgrass, (v) switchgrass, (vi) reed plants, (vii) Jerusalem artichoke, and (viii) sorghum.

Short rotation coppice (or SRC) refers to fast-growing deciduous trees which are grown as energy crops, such as willow and poplar trees. The species of short rotation coppice that are most suitable, and therefore most popular, for use as energy crops are poplar and willow (and possibly also birch) because they both require deep, moisture-retentive soils for proper growth. Willow, in particular, is able to endure periods of water logging and is therefore better suited to wetter soils.

Miscanthus is a hardy perennial rhizomatous grass that produces a crop of bamboo-like cane up to 14 feet tall. Rhizomatous implies that it spreads naturally by means of underground storage organs (rhizomes). Miscanthus can grow up to ten feet tall and theoretically can give an annual harvest of up to 12 tons per acre. Like other bioenergy crops, the harvested stems of miscanthus may be used as fuel for production of heat and electric power, or for conversion to other useful products such as ethanol. Miscanthus is high in lignin and lignocellulose fiber and uses the C4 pathway. It can be grown in a cool climate and on many types of arable land. Miscanthus does not require a big input of fertilizers due to its capability to recycle large amounts of nutrients.

Miscanthus has a similar calorific value per unit weight as wood and therefore could possibly be used in the same power plant or those designed for agricultural residues.

Reed canary grass is a robust C3 perennial grass, widely distributed across temperate regions of Europe, Asia, and also North America. It usually grows in damp areas.

This rhizomatous grass can grow up to six feet in height and usually flowers in June and July. Reed canary grass is usually harvested once per year either by mowing or baling using a high density baler. Crop duration of 10 years or more may be possible. Due to its low moisture content, canary grass (those harvested in spring) can be easily converted to pellets, briquettes, and powder.

Cordgrasses are perennial grasses from Western Europe, Africa and North America. They are pioneer colonists of muddy coastal salt flats, spreading by means of rhizomes to form clumps and mats which help to reduce erosion and reclaim land from the sea. Cordgrasses are expected to be able to produce good yields of biomass in poor soil conditions.

Switchgrass is a perennial sod-forming grass with thick strong stems. The advantages of switchgrass as an energy crop are that it is fast-growing, remarkably adaptable, and high-yielding. Further advantages of switchgrass are that it can be harvested, using conventional equipment, either annually or semi-annually for 10 years or more before replanting is needed and that it is able to reach deep into the soil for water and use water very efficiently.

The utilization of energy crops such as switchgrass (*Panicum virgatum*, L., Poaceae) is a concept with great relevance to current ecological and economic issues on a global scale. Development of a significant national capacity to utilize perennial forage crops, such as switchgrass as biofuels, could provide an important new source of energy from perennial cropping systems, which are compatible with conventional farming practices, would help reduce degradation of agricultural soils, and lower national dependence on foreign oil.

Reed plants are a potentially prolific producer of biomass, capable of yielding 20-25 t per ha of dry matter annually for a number of years. They can grow up to 6 m, are spread by means of stout rhizomes and stolons, and are commonly found in swampy ground and shallow water throughout temperate and subtropical areas.

The high-fructose syrups that can be derived from the tubers produced by the Jerusalem artichoke may be used for the production of ethanol and other industrial raw materials. Jerusalem Artichokes also produce a large amount of top growth which may also prove to be a useful source of biomass for energy purposes.

Sorghum is an annual tropical grass with large genetic variation that is a crop with the potential for energy production. Sweet sorghum has been selected for its sugar content and is normally grown for molasses production. Forage sorghum has been selected for high yields of reasonably good-quality animal feed. Sorghum varieties producing tall plants with large stems make the best candidates for biomass production. Both sweet and forage sorghum have a high potential for lodging. Lodging can result in harvest problems with ensuing loss of yield from both initial and ratoon crops.

Sweet sorghums produce sugar syrups which could form the basis of fermentation processes for methane or ethanol production, and some of the forage types of the plant may be suitable for biomass production.

Hemp is an annual short day, C3 plant with a high cellulose and lignin content in its stems and a high fat and protein content in its seeds. The entire plant consisting of bast fibers, leaves, seeds, and processable remains can be used as a solid fuel when compacted. The stalk contains a strong and durable fiber. The average height is on the order of 7 feet, but the hemp stalk can reach up to 12 feet in height. For the energetic use, the whole hemp crop is harvested.

Hemp can be easily planted and cultivated, but its growing is prohibited in many countries as it can be used as a drug. The plants vegetative period is approximately 100 days, with the main growth period in summer months followed by flowering in toward the end of summer. The yields are high, but the high plant moisture content can create storage problems. Two different harvesting technologies are available for the energy use of the whole hemp crop.

The first is the whole-fiber-technology where, with a modified chopping technology, the hemp culm is cut into 24 to 24-inch lengths. The straw stays for four weeks on the field for drying before the bales are pressed. Another technology is wet harvesting. This technology includes the chopping of the crops followed by silaging. For combustion, it is necessary to press the hemp silage into bales to reduce the water content of the fuel.

All crops, including some biennial, permanent, and multiannual crops, are produced for energy purposes. Energy is generated by burning plants grown for the purpose, often after the dry matter is pelletized. Energy crops are used for firing power plants, either alone or co-fired with other fuels. Alternatively, they may be used for heat or combined heat and power (CHP) production.

Energy Crops – Grasses

Grasses are usually herbaceous plants with narrow leaves growing from the base. They include the true grasses of the Poaceae (or Gramineae) family, as well as the sedges (Cyperaceae) and the rushes (Juncaceae). The true grasses include cereals, bamboo and the grasses of lawns (turf), and grassland. Sedges include many wild marsh and grassland plants, and some cultivated ones such as water chestnut (*Eleocharis dulcis*) and papyrus sedge (*Cyperus papyrus*). Most of the interest in grass biomass tends to focus on economics, but there is a list of traits that should be considered and valued when evaluating a potential solid biomass energy source. These traits are beneficial to society in general, or impact the suitability of biomass for a farm operation.

Miscanthus is a tall hardy perennial rhizomatous grass that produces a crop of bamboo-like cane up to 4 meters tall and which has been evaluated in Europe during the past 5-10 years as a new bioenergy crop. Like other energy crops, the harvested stems of miscanthus may be used as fuel for production of heat and electric power, or for conversion to other useful products such as ethanol.

The fact is that miscanthus *rhizomatous* implies that it spreads naturally by means of underground storage organs (rhizomes). Miscanthus can grow up to ten feet tall and theoretically can give an annual harvest of up to 12 tons per acre. Like other bioenergy crops, the harvested stems of miscanthus may be used as fuel for production of heat and electric power, or for conversion to other useful products such as ethanol. Miscanthus is high in lignin and

lignocellulose fiber and uses the C4 pathway. It can be grown in a cool climate and on many types of arable land. Miscanthus does not require a big input of fertilizers due to its capability to recycle large amounts of nutrients. Miscanthus has a similar calorific value per unit weight as wood and therefore could possibly be used in the same power plant or those designed for agricultural residues.

Switchgrass is a perennial sod-forming grass with thick strong stems. The advantages of switchgrass as an energy crop are that it is fast-growing, remarkably adaptable, and high-yielding. Further advantages of switchgrass are that it can be harvested, using conventional equipment, either annually or semi-annually for 10 years or more before replanting is needed and that it is able to reach deep into the soil for water and use water very efficiently.

Switchgrass is a perennial grass native to North America. Switchgrass makes for a great energy crop because it grows fast, capturing lots of solar energy and turning it into chemical energy which it stores as cellulose.

Switchgrass has the potential to be a versatile bioenergy feedstock since the energy content is comparable to that of wood with significantly lower initial moisture content. Switchgrass is a very suitable substrate and produces high ethanol yield using current simultaneous saccharification and fermentation technology. Extensive analysis of ash and alkali content of switchgrass indicates that it typically has relatively low alkali content and should have low slagging potential in coal-fired combustion systems. As an agro-fiber source for pulping, switchgrass has a relatively high cellulose content, low ash content, and good fiber length-to-width ratios. Switchgrass reaches its full yield potential after the third year planted, producing approximately 6 to 8 tons per acre; that is 500 gallons of ethanol per acre.

The utilization of energy crops such as *switchgrass* (*Panicum virgatum*, L., Poaceae) is a concept with great relevance to current ecological and economic issues on a global scale. Development of a significant national capacity to utilize perennial forage crops, such as switchgrass as biofuels, could provide an important new source of energy from perennial cropping systems, which are compatible with conventional farming practices, would help reduce degradation of agricultural soils, and lower national dependence on foreign oil.

Energy Crops – Oilseed Crops

Oilseed crops are diverse in the plant kingdom and belong to several families and include plants such as soybean and canola (rapeseed). Soybean and groundnut are members of the legume family Fabaceae (Leguminosae) and have been grown in rotation, with other crops benefiting from the nitrogen fixation feature of soybean and groundnut. Rhizobium and related genera in the root nodules of legumes fix atmospheric nitrogen. Much of the nitrogen remains in the soil and is available for subsequent crops. These crops have the ability to produce oil within the seeds, and the oil can be pressed out of the ripe seed.

Oilseed crops are grown throughout the world for use as vegetable and industrial oils, spices, and birdfeed. In a region dominated by winter and spring wheat, the acceptance and production of another crop requires that it has an agronomic benefit to the cropping system. Canola (*Brassica* sp.), mustard (*B. juncea* and *Sinapis alba* L.), and flax (*Linum usitatissimum* L.) are well-adapted to cool, short-season conditions found on the Canadian prairies and northern Great Plains border states of the United States. Sunflower (*Helianthus annuus* L.) and safflower (*Carthamus tinctorius* L.) are better adapted to the longer growing season and warmer temperatures.

Thus, oilseeds constitute an important group of commercial crops, and rapeseed mustard, groundnut, sesame, linseed, and castor, are major crops.

See also: Canola Oil, Energy Crops, Soybeans.

Energy Crops – Residual Herbaceous Biomass

Herbaceous energy crops such as the woody, perennial, rhizomatous grasses like miscanthus offer the advantage of an annual harvest.

Residual herbaceous biomass (straw) is the main residual herbaceous material for energy application. As it is a residual product, its availability for energy purposes is driven by the cereal markets and does not have autonomous market behavior. In addition, farms consume significant quantities of straw internally – as bed material for livestock,

grain drying, etc. Some straw is also chaffed and returned back to the field as a soil ameliorator. The net straw yield per hectare for energy application also depends on the crop, the grain yield per hectare, climate and cultivation conditions, etc. Nevertheless, one can roughly estimate that the average straw yield per hectare is approximately 50 to 65% of the grain yield per hectare from cereals and oilseeds.

Similar to herbaceous crops, straw usually has lower moisture content than woody biomass. Conversely, it has a lower calorific value, bulk density, ash melting point and higher content of ash, and problematic inorganic component such as chlorine, potassium, and sulfur, which cause corrosion and pollution. The last two drawbacks can be relatively easily overcome by leaving straw on the field for a while. In such a way, rainfall “washes” it naturally from a large part of potassium and chlorine. Alternatively, fresh straw can be directly shipped to the gasification plant, where it is washed by dedicated facilities at moderate temperatures (50 to 60°C; 120 to 140°F). Due to washing, the initially low moisture content of straw becomes higher in both cases and hence, a mandatory drying is applied afterwards. In both cases also, the content of corrosive components is reduced, but not completely taken out. In order to decrease handling costs, straw and dedicated herbaceous energy crops are usually baled before being shipped to the gasification plant. The weight and the size of bales depend on the baling equipment and on the requirements of the gasification plant.

In starch crops, most of the six-carbon sugar units are linked together in long, branched chains (starch). Yeast cannot use these chains to produce ethanol. The starch chains must be broken down into individual six-carbon units or groups of two units. The starch conversion process is relatively simple because the bonds in the starch chain can be broken in an inexpensive manner by the use of heat and enzymes, or by a mild acid solution.

See also: Energy Crops.

Energy Crops – Short Rotation Woody Crops

Short rotation energy crops that are harvested on a cycle of anything from 2 to 20 years, depending on the crop and the system, and herbaceous energy crops that are harvested annually.

Short rotation woody crops (short rotation coppice or SRC) refers to fast-growing deciduous trees which are grown as energy crops, such as willow and poplar trees. The species of SRC that are most suitable, and therefore most popular, for use as energy crops are poplar and willow (and possibly also birch) because they both require deep, moisture-retentive soils for proper growth. Willow, in particular, is able to endure periods of water logging and is therefore better suited to wetter soils.

See also: Energy Crops.

Energy Crops – Sugar Crops

Sugar crops include a variety of plants such as fodder beets, fruit crops, Jerusalem artichokes, sugar beets, sugar cane, and sweet sorghum. Interest in ethanol production from such agricultural crops has prompted the development of sugar crops that have not been cultivated on a widespread commercial basis in many countries. Preparation is basically a crushing and extraction of the sugars which the yeast can immediately use. But sugar crops must be dealt with fairly quickly before their high sugar and water content causes spoilage. Because of the danger of such spoilage, the storage of sugar crops is not practical.

The fodder beet is a high-yielding forage crop obtained by crossing two other beet species, sugar beets and mangolds. It is similar in most agronomic respects to sugar beets. The attraction of this crop lies in its higher yield of fermentable sugars per acre relative to sugar beets and its comparatively high resistance to loss of fermentable sugars during storage.

Fruit crops (e.g., grapes, apricots, peaches, and pears) are another type of feedstock in the sugar crop category. Typically, fruit crops such as grapes are used as the feedstock in wine production. These crops are not likely to be used as feedstocks for production of fuel-grade ethanol because of their high market value for direct human consumption. However, the co-products of processing fruit crops are likely to be used as feedstocks because fermentation is an

economical method for reducing the potential environmental impact of untreated wastes containing fermentable sugars.

The Jerusalem artichoke has shown excellent potential as an alternative sugar crop. A member of the sunflower family, this crop is native to North America and well-adapted to northern climates. Like the sugar beet, the Jerusalem artichoke produces sugar in the top growth and stores it in the roots and tuber. It can grow in a variety of soils, and it is not demanding of soil fertility. The Jerusalem artichoke is a perennial plant; small tubers left in the field will produce the next season's crop, so no ploughing or seeding is necessary.

Although sugar beets are grown in many areas of the U.S., they must be rotated with non-root crops: (1 beet crop per 4 year period is the general rule). While beet by-products cannot provide fuel for the distillery, the beet pulp and tops are excellent feed in wet or dry form. Or the tops may be left on the field for fertilizer and erosion control.

Sugar cane produces high yields per acre of both sugar and crop residue which are strong points of sugar cane production. The crop residue, called bagasse, is used in Brazil to provide heat for the distilleries.

Sweet sorghum is a name given to varieties of a species of sorghum. This crop has been cultivated on a small scale in the past for production of table syrup, but other varieties can be grown for production of sugar. The most common types of sorghum species are those used for production of grain. Sweet sorghum can be considered as an energy crop, because it can be grown in all continents, in tropical, sub-tropical, temperate regions as well as in poor-quality soils. Sweet sorghum is a warm-season crop that matures earlier under high temperatures and short days. Sweet sorghum is an extraordinarily promising multifunctional crop not only for its high economic value but also for its capacity to provide a very wide range of renewable energy products, industrial commodities, food, and animal feed products. Sweet sorghum biomass is rich in readily fermentable sugars, and thus it can be considered as an excellent raw material for fermentative hydrogen production. Integrated production of several crops (sweet sorghum/sugar-cane/sweet sorghum corn/sweet sorghum/ sweet potatoes), and simultaneous processing of the full crop components (starch, sugar, lignocellulosic) can improve the global economics of bioenergy schemes considerably in view of a viable production of bioethanol.

See also: Energy Crops.

Energy Density

The energy density is the amount of energy stored in a system or region of space per unit volume. It may also be used for energy per unit mass, though the accurate term for this is specific energy. Often, only the useful or extractable energy is measured. Energy per unit volume has the same physical units as pressure.

There are several different types of energy content. One is the theoretical total amount of thermodynamic work that can be derived from a system, with a given temperature and pressure for the surroundings – this is referred to as the exergy of the system.

In terms of energy content and energy density, there are two kinds of heat of combustion: (i) the higher value (HHV), or gross heat of combustion, includes all the heat released as the products cool to room temperature and whatever water vapor is present condenses, and (ii) the lower value (LHV), or net heat of combustion, does not include the heat which could be released by condensing water vapor, and may not include the heat released on cooling all the way down to room temperature.

See also: Heat Content.

Energy-Efficiency Ratio

Fuel efficiency is the efficiency of a process that converts chemical potential energy contained in a carrier fuel into energy. Overall fuel efficiency may vary per device, which in turn may vary per application, and this spectrum of variance is often illustrated as a continuous energy profile.

The energy efficiency ratio is a number which represents the energy stored in a fuel as compared to the energy required to produce, process, transport, and distribute that fuel. The specific energy content of a fuel is the heat

energy obtained when a certain quantity is burned (such as a gallon, liter, kilogram). The specific energy content is also known as the heat of combustion.

There exist two different values of specific heat energy for the same batch of fuel – one is the high (or gross) heat of combustion, and the other is the low (or net) heat of combustion. The high value is obtained when, after the combustion, the water in the exhaust is in liquid form. For the low value, the exhaust has all the water in vapor form (steam). Since water vapor gives up heat energy when it changes from vapor to liquid, the high value is larger since it includes the latent heat of vaporization of water. The difference between the high and low values is significant, approximately 8 or 9%. This accounts for most of the apparent discrepancy in the heat value of gasoline.

Energy Production from Crops

There are four basic types of processes used to generate energy from crops: direct combustion, gasification, pyrolysis, and anaerobic digestion.

Direct combustion involves burning the energy crop and then using the resulting hot combustion gases to raise steam. The steam is, in turn, used to drive a steam turbine which drives a generator to produce electricity. The conversion efficiency from energy crop to energy is fairly low, especially for small systems, but this is balanced by the relatively low capital cost of direct combustion systems and the fact that the technology is tried and tested. Furthermore, using the waste heat produces much better efficiencies and economics.

Combustion facilities can burn many types of biomass fuel, including wood, agricultural residues, wood pulping liquor, municipal solid waste (MSW), and refuse-derived fuel. Combustion technologies convert biomass fuels into several forms of useful energy for commercial or industrial uses: hot air, hot water, steam, and electricity.

A furnace is the simplest combustion technology. In a furnace, biomass fuel burns in a combustion chamber, converting biomass into heat energy. As the biomass burns, hot gases are released. These hot gases contain approximately 85% of the fuel's potential energy. Commercial and industrial facilities use furnaces for heat, either directly or indirectly through a heat exchanger in the form of hot air or water.

A biomass-fired boiler is a more adaptable direct combustion technology because a boiler transfers the heat of combustion into steam. Steam can be used for electricity, mechanical energy, or heat. Biomass boilers supply energy at low cost for many industrial and commercial uses.

Pile burners consist of cells, each having an upper and a lower combustion chamber. Biomass fuel burns on a grate in the lower chamber, releasing volatile gases. The gases burn in the upper (secondary) combustion chamber, and pile burners must be shut down periodically to remove ash.

Although capable of handling high-moisture fuels and fuels mixed with dirt, pile burners have become obsolete with the development of more efficient combustion designs with automated ash removal systems.

In a stationary or traveling grate combustor, an automatic feeder distributes the fuel onto a grate, where the fuel burns. Combustion air enters from below the grate. In the stationary grate design, ashes fall into a pit for collection. In contrast, a traveling grate system has a moving grate that drops the ash into a hopper.

Fluidized-bed combustors burn biomass fuel in a hot bed of granular material, such as sand. Injection of air into the bed creates turbulence resembling a boiling liquid. The turbulence distributes and suspends the fuel. This design increases heat transfer and allows for operating temperatures below 972°C (1,700°F), reducing nitrogen oxide (NO_x) emissions. Fluidized-bed combustors can handle high-ash fuels and agricultural biomass residue.

Conventional combustion equipment is not designed for burning agricultural residues. Straw and grass contain alkali (potassium and sodium) compounds, which are also present in all annual crops and crop residues and in the annual growth of trees and plants. During combustion, alkali combines with silica, which is also present in agricultural residues. This reaction causes slagging and fouling problems in conventional combustion equipment designed for burning wood at higher temperatures.

Volatile alkali lowers the fusion temperature of ash. In conventional combustion equipment having furnace gas exit temperatures above 780°C (1,450°F), combustion of agricultural residue causes slagging and deposits on heat transfer surfaces. Specially designed boilers with lower furnace exit temperatures could reduce slagging and fouling from combustion of these fuels. Low-temperature gasification may be another method of using these fuels for efficient energy production while avoiding the slagging and fouling problems encountered in direct combustion.

Combustion facilities that produce electricity from steam-driven turbine-generators have a conversion efficiency on the order of 17 to 25%. Using a boiler to produce both heat and electricity (cogeneration) improves overall system efficiency to as much as 85%. That is, cogeneration converts 85% of the fuel's potential energy into useful energy in two forms: electricity and steam heat.

Two cogeneration arrangements, or cycles, are possible for combining electric power generation with industrial steam production. Steam can be used in an industrial process first and then routed through a turbine to generate electricity. This arrangement is called a bottoming cycle. In the alternate arrangement, steam from the boiler passes first through a turbine to produce electric power. The steam exhaust from the turbine is then used for industrial processes or for space and water heating. This arrangement is called a topping cycle.

The direct-fired gas turbine is another combustion technology for converting biomass to electricity. In this technology, fuel pretreatment reduces biomass to a particle size of less than 2 millimeters and a moisture content of less than 25%. Then, the fuel is burned with compressed air. Cleanup of the combustion gas reduces particulate matter before the gas expands through the turbine stage. The turbine drives a generator to produce electricity.

Co-firing biomass as a secondary fuel in a coal-burning power plant using high-sulfur coal could help reduce sulfur dioxide and nitrogen oxide emissions. Also, co-firing decreases net carbon dioxide emissions from the power plant (if the biomass fuel comes from a sustainable source). Co-firing may require wood fuel preparation or boiler modifications to maintain boiler efficiency.

Gasification is a high temperature process which produces gas which can then be used in an internal combustion engine or fuel cell.

Briefly, gasification was used as long ago as the early 1800s. The process was rather crude, and the fuel was most often coal. The gas product (town gas) was used for heating and lighting. For example, the gas was piped to street lights as early as 1846 in England.

The gasification process produces a fuel gas from crops by heating them under carefully controlled temperature, pressure, and atmospheric conditions. A key to gasification is using less air or oxygen than is usually found in combustor. The product (biogas or fuel gas), like natural gas, can be burned in high-efficiency gas turbines.

The gasifier is the heart of the gasification process. Gasifiers are designed to process the fuel in a variety of ways consistent with the type of fuel, the end use of the gas, the size of the process, and the source of oxygen. The oxygen may be introduced as a pure gas or may come from air or steam. Some gasifiers operate under pressure; others do not.

The simplest type of gasifier is the fixed bed countercurrent gasifier. The biomass is fed at the top of the reactor and moves downwards as a result of the conversion of the biomass and the removal of ashes. The air intake is at the bottom, and the gas leaves at the top. The biomass moves in countercurrent to the gas flow, and passes through the drying zone, the distillation zone, reduction zone, and the oxidation zone.

The major advantages of this type of gasifier are its simplicity, high charcoal burn-out, and internal heat exchange leading to low gas exit temperatures and high gasification efficiency. In this way also, fuels with high moisture content (up to 50 % w/w) can be used. The major drawbacks are the high amounts of tar and pyrolysis products because the pyrolysis gas is not led through the oxidation zone. This is of minor importance if the gas is used for direct heat applications, in which the tars are usually burnt. In case the gas is used for engines, gas cleaning is required, resulting in problems of tar-containing condensates.

In the conventional downdraft gasifier (sometimes called the co-flow gasifier), biomass is fed at the top of the reactor and air intake is at the top or from the sides. The gas leaves at the bottom of the reactor, so the fuel and the gas move in the same direction. The pyrolysis gasses are lead through the oxidation zone (with high temperatures) and/or more or less burnt or cracked. Therefore, the producer gas has low tar content and is suitable for engine applications. In practice, however, a tar-free gas is seldom if ever achieved over the whole operating range of the equipment. Because of the lower level of organic components in the condensate, downdraft gasifiers suffer less from environmental objections than updraft gasifiers.

Successful operation of a downdraft gasifier requires drying the biomass fuel to a moisture content of less than 20%. The advantage of the downdraft design is the low tar content of the producer gas. However, the disadvantages of the downdraft gasifier are (i) the high amounts of ash and dust particles in the gas, (ii) the inability to operate on a number of unprocessed fuels, often pelletization or briquetting of the biomass is necessary, (iii) the outlet gas has a high temperature leading to a lower gasification efficiency, and (iv) the moisture content of the biomass must be less than 25% by weight.

A more recent development is the open core gasifier design for gasification of small sized biomass with high ash content. The producer gas is not tar-free; it contains approx. 0.05 kg tar per kg gas. In the open core gasifier, the air is sucked over the whole cross section from the top of the bed. This facilitates better oxygen distribution since the oxygen will be consumed over the whole cross section, so that the solid bed temperature will not reach the local extremes (hot spots) observed in the oxidation zone of conventional gasifiers due to poor heat transfer. Moreover, the air nozzles in conventional gasifiers generate caves and create obstacles that may obstruct solid flow – especially for solids of low bulk such as rice husk. On the other hand, the entry of air through the top of the bed creates a downward flow of the pyrolysis gases, and transports the tar products to the combustion zone. Thus, flow problems due to the caking of rice husk caused by back mixing of tar are avoided.

The gasification process is amenable to a variety of biomass feedstocks such as waste rice hulls, wood waste, grass, and the dedicated energy crops. Gasification is a clean process with few air emissions and, when crops are used as the feedstock, little or no ash.

In the gasifier, biomass is converted into a gaseous mixture of hydrogen, carbon monoxide, carbon dioxide, and other compounds by applying heat under pressure in the presence of steam and a controlled amount of oxygen. The biomass produces synthesis gas.

The above reaction uses glucose as a surrogate for cellulose. Biomass has highly variable composition and complexity, with cellulose as one major component.

The gasification process could play a significant role in meeting the goal of greenhouse gas mitigation. It is likely that both in the transition phase to a hydrogen economy and in the steady state, a significant fraction of hydrogen might be derived from domestically abundant crops.

In addition to the co-firing applications of crops (and other biomass) biomass with coal, biomass can provide up to 15% of the total energy input of the fuel mixture. Such concepts address greenhouse gas mitigation by co-firing biomass and coal to offset the losses of carbon dioxide to the atmosphere that are inherent in coal combustion processes (even with the best-engineered capture and storage of carbon). Since growth of biomass fixes atmospheric carbon, its combustion leads to no net addition of atmospheric carbon dioxide even if vented. Thus, co-firing of crops or crop residues (or other biomass with coal) in an efficient coal gasification process, affording the opportunity for capture and storage of carbon dioxide, could lead to a net reduction of atmospheric carbon dioxide. Cheaper, though less plentiful, biomass residue could supplant crops as gasifier feedstock leading to a less significant impact on the environment than would farming bioenergy crops.

Along similar lines, willow biomass crops have been shown to be a good fuel for farm-based power production using advanced gasification technology. The fuel gas can be used for generating electricity, using micro-turbines modified to operate on low-BTU gas, or for other farm energy needs. Willow biomass was found to make a fuel for ash-rejection gasifiers with a predicted net gasification efficiency of approximately 85%. Analysis showed that developing a method to co-gasify willow with various amounts of low-cost wastes, such as dairy farm animal waste, can be an excellent way to reduce the fuel cost, to increase the overall fuel availability, and to help work around problems resulting from seasonal availability of bioenergy crops. Co-gasification of dairy farm wastes along with willow offers an economical way to dispose of the wastes and manage nutrient flows on a dairy farm.

Agricultural residues can be divided into two groups, and these are (i) crop residues and (ii) agro-industrial residues. Crop residues are plant materials left behind in the farm after removal of the main crop produce. The remaining materials could be of different sizes, shapes, forms, and densities like straw, stalks, sticks, leaves, haulms, fibrous materials, roots, branches, and twigs.

Due to high energy content, straw is one of the best crop residues for solid biofuels. However, straw has several disadvantages – it has a higher ash content, which results in lower calorific value. In order to improve its bulk density, the straw is generally baled before transportation. Straw burning requires a specific technology. There are four basic types of straw burners: those that accept shredded, loose straw; burners that use densified straw products such as pellets, briquettes or cubes, and straw logs; small, square bale burners and round bale burners. To be suitable for heat and electricity production, straw should not have a large content of moisture, preferably not more than 20% as

the moisture reduces the boiler efficiency. Also, straw color as well as straw chemistry should be considered before burning as it indicates the quality of the straw.

The agro-industrial residues are by-products of the post-harvest processes of crops such as cleaning, threshing, sieving, and crushing. These could be in the form of husk, dust, and straw. Furthermore, the quantity of agricultural residues produced differs from crop to crop and is affected by soil type and irrigation conditions. Production of agricultural residues is related to the corresponding crop production and ratio between the main crop produce and the residues, which varies from crop to crop and, at times, with the variety of the seeds in one crop itself. Thus, for known amounts of crop production, it may be possible to estimate the amounts of agricultural residues produced using the residue-to-crop ratio.

Most crop or agricultural residues are not found throughout the year but are available only at the time of harvest. The amount available depends upon the harvesting time, storage-related characteristics, and the storage facility.

Pyrolysis is a medium temperature method which produces gas, oil, and char from crops which can then be further processed into useful fuels or feedstock.

Pyrolysis is often considered to be the gasification of biomass in the absence of oxygen. However, the chemistry of each process may differ significantly. In general, biomass does not gasify as easily as coal, and it produces other hydrocarbon compounds in the gas mixture exiting the gasifier; this is especially true when no oxygen is used. As a result, typically an extra step must be taken to reform these hydrocarbon derivatives with a catalyst to yield a clean syngas mixture of hydrogen, carbon monoxide, and carbon dioxide.

Fast pyrolysis is a thermal decomposition process that occurs at moderate temperatures with a high heat transfer rate to the biomass particles and a short hot vapor residence time in the reaction zone. Several reactor configurations have been shown to assure this condition and to achieve yields of liquid product as high as 75% based on the starting dry biomass weight. They include bubbling fluid beds, circulating and transported beds, cyclonic reactors, and ablative reactors.

Fast pyrolysis of biomass produces a liquid product, pyrolysis oil or bio-oil that can be readily stored and transported. Pyrolysis oil is a renewable liquid fuel and can also be used for production of chemicals. Fast pyrolysis has now achieved a commercial success for production of chemicals and is being actively developed for producing liquid fuels. Pyrolysis oil has been successfully tested in engines, turbines, and boilers, and been upgraded to high-quality hydrocarbon fuels.

Direct hydrothermal liquefaction involves converting biomass to an oily liquid by contacting the biomass with water at elevated temperatures (300 to 350°C) with sufficient pressure to maintain the water primarily in the liquid phase (12 to 20 MPa) for residence times up to 30 minutes. Alkali may be added to promote organic conversion. The primary product is an organic liquid with reduced oxygen content (approximately 10%), and the primary by-product is water containing soluble organic compounds.

The importance of the provisions for the supply of feedstocks as crops and other biomass are often underestimated since it is assumed that the supplies are inexhaustible. While this may be true over the long term, short-term supply of feedstocks can be as much as risk as any venture.

Anaerobic digestion is a natural process and is the microbiological conversion of organic matter to methane in the absence of oxygen. The decomposition is caused by natural bacterial action in various stages and occurs in a variety of natural anaerobic environments, including water sediment, water-logged soils, natural hot springs, ocean thermal vents, and the stomach of various animals (e.g., cows). The digested organic matter resulting from the anaerobic digestion process is usually called digestate.

Symbiotic groups of bacteria perform different functions at different stages of the digestion process. There are four basic types of microorganisms involved. Hydrolytic bacteria break down complex organic wastes into sugars and amino acids. Fermentative bacteria then convert those products into organic acids. Acidogenic microorganisms convert the acids into hydrogen, carbon dioxide, and acetate. Finally, the methanogenic bacteria produce biogas from acetic acid, hydrogen, and carbon dioxide.

The process of anaerobic digestion occurs in a sequence of stages involving distinct types of bacteria. Hydrolytic and fermentative bacteria first break down the carbohydrates, proteins and fats present in biomass feedstock into fatty acids, alcohol, carbon dioxide, hydrogen, ammonia, and sulfides. This stage is called hydrolysis (or liquefaction).

Next, acetogenic (acid-forming) bacteria further digest the products of hydrolysis into acetic acid, hydrogen, and carbon dioxide. Methanogenic (methane-forming) bacteria then convert these products into biogas.

The combustion of digester gas can supply useful energy in the form of hot air, hot water, or steam. After filtering and drying, digester gas is suitable as fuel for an internal combustion engine, which, combined with a generator, can

produce electricity. Future applications of digester gas may include electric power production from gas turbines or fuel cells. Digester gas can substitute for natural gas or propane in space heaters, refrigeration equipment, cooking stoves, or other equipment. Compressed digester gas can be used as a renewable transportation fuel.

Digestion can be either wet or dry. Dry digestion refers to mixtures which have a solid content of 30% or greater, whereas wet digestion refers to mixtures of 15% or less.

In recent years, increasing awareness that anaerobic digesters can help control the disposal and odor of animal waste has stimulated renewed interest in the technology. New digesters now are being built because they effectively eliminate the environmental hazards of dairy farms and other animal feedlots.

Anaerobic digester systems can reduce fecal coliform bacteria in manure by more than 99%, virtually eliminating a major source of water pollution. Separation of the solids during the digester process removes approximately 25% of the nutrients from manure, and the solids can be sold out of the drainage basin where nutrient loading may be a problem. In addition, the digester's ability to produce and capture methane from the manure reduces the amount of methane that otherwise would enter the atmosphere. Scientists have targeted methane gas in the atmosphere as a contributor to global climate change.

Controlled anaerobic digestion requires an airtight chamber, called a digester. To promote bacterial activity, the digester must maintain a temperature of at least 20°C (68°F). Using higher temperatures, up to 65°C (150°F), shortens processing time and reduces the required volume of the tank by 25% to 40%. However, there are more species of anaerobic bacteria that thrive in the temperature range of a standard design (mesophilic bacteria) than there are species that thrive at higher temperatures (thermophilic bacteria). High-temperature digesters also are more prone to upset because of temperature fluctuations, and their successful operation requires close monitoring and diligent maintenance.

The biogas produced in a digester (digester gas) is actually a mixture of gases, with methane and carbon dioxide making up more than 90% of the total. Biogas typically contains smaller amounts of hydrogen sulfide, nitrogen, hydrogen, methyl mercaptans, and oxygen. Methane is a combustible gas. The energy content of digester gas depends on the amount of methane it contains. Methane content varies from approximately 55% to 80%. Typical digester gas, with a methane concentration of 65%, contains approximately 600 Btu of energy per cubic foot.

There are three basic digester designs, and all of them can trap methane and reduce fecal coliform bacteria, but they differ in cost, climate suitability, and the concentration of manure solids they can digest.

A covered lagoon digester, as the name suggests, consists of a manure storage lagoon with a cover. The cover traps gas produced during decomposition of the manure. This type of digester is the least expensive of the three.

Covering a manure storage lagoon is a simple form of digester technology suitable for liquid manure with less than 3% solids. For this type of digester, an impermeable floating cover of industrial fabric covers all or part of the lagoon. A concrete footing along the edge of the lagoon holds the cover in place with an airtight seal. Methane produced in the lagoon collects under the cover. A suction pipe extracts the gas for use. Covered lagoon digesters require large lagoon volumes and a warm climate. Covered lagoons have low capital cost, but these systems are not suitable for locations in cooler climates or locations where a high water table exists.

A complete mix digester converts organic waste to biogas in a heated tank above or below ground. A mechanical or gas mixer keeps the solids in suspension. Complete mix digesters are expensive to construct and cost more than plug-flow digesters to operate and maintain.

Complete mix digesters are suitable for larger manure volumes having solids concentration of 3% to 10%. The reactor is a circular steel or poured concrete container. During the digestion process, the manure slurry is continuously mixed to keep the solids in suspension. Biogas accumulates at the top of the digester. The biogas can be used as fuel for an engine-generator to produce electricity or as boiler fuel to produce steam. Using waste heat from the engine or boiler to warm the slurry in the digester reduces retention time to less than 20 days.

Plug-flow digesters are suitable for ruminant animal manure that has a solids concentration of 11% to 13%. A typical design for a plug-flow system includes a manure collection system, a mixing pit, and the digester itself. In the mixing pit, the addition of water adjusts the proportion of solids in the manure slurry to the optimal consistency. The digester is a long, rectangular container, usually built below-grade, with an airtight, expandable cover.

New material added to the tank at one end pushes older material to the opposite end. Coarse solids in ruminant manure form a viscous material as they are digested, limiting solids separation in the digester tank. As a result, the material flows through the tank in a plug. The average retention time (the time a manure plug remains in the digester) is 20 to 30 days. Anaerobic digestion of the manure slurry releases biogas as the material flows through the

digester. A flexible, impermeable cover on the digester traps the gas. Pipes beneath the cover carry the biogas from the digester to an engine-generator set.

A plug-flow digester requires minimal maintenance. Waste heat from the engine-generator can be used to heat the digester. Inside the digester, suspended heating pipes allow hot water to circulate. The hot water heats the digester to keep the slurry at 25°C to 40°C (77°F to 104°F), a temperature range suitable for methane-producing bacteria. The hot water can come from recovered waste heat from an engine generator fueled with digester gas or from burning digester gas directly in a boiler.

Energy Production from Wood

Combustion remains the most common way of converting biomass into energy. It is well understood, relatively straightforward and commercially available, and can be regarded as a proven technology. However, the desire to burn uncommon fuels, improve efficiencies, cut costs, and decrease emission levels results in new technologies being continuously developed.

On the other hand, wood as a feedstock for storing solar energy, is a renewable energy source. It is a relatively clean, efficient, safe energy source having low sulfur content and is generally found throughout the country. Its primary products of combustion are carbon dioxide, water vapor, and ash. The ash content is low (typically 1-2% w/w) and that which does remain can be used as a worthwhile soil conditioner.

A wood fire is easy to start and produces a large quantity of heat in a short time as well as adding a cheerful atmosphere to the home. An ample air supply to the wood fire is important to ensure complete burning of combustible gases. Wood fires are ideal where heat is required only occasionally, for warming a living area on cool days or for supplying extra heat in extremely cold weather. When considering wood as a primary heat source, several factors must be carefully weighed to ensure satisfactory results and acceptable deficiencies.

Generally, hardwoods which provide long-burning fires contain the greatest total heating value per unit of volume. Softwoods which give a fast-burning, cracking blaze are less dense and contain less total heating value per unit of volume. However, the amount and types of wood fuel used vary considerably between regions, mainly due to different local situations and conditions.

Charcoal continues to be used as an important industrial source of energy for use in heavy industry, such as steel and alloy production. The industrial demand for charcoal in the last few years has led to new, more efficient and large-scale technologies, mainly aimed at improving charcoal yield and quality.

On the other hand, the production and consumption of black liquor, which is a by-product of pulp and paper production, are concentrated in developed countries with large paper industries. In the pulp and paper industry, black liquors are widely used for heat and power production. Almost all of the energy needs for industry are met by black liquors, with surplus electricity being sold to the public grid in some cases. A combination of factors such as higher oil prices and technological developments in wood fuel production, transportation, and combustion is also making wood fuels more attractive.

Combustion remains the most common way of converting biomass into energy. It is well understood, relatively straightforward and commercially available, and can be regarded as a proven technology. However, the desire to burn uncommon fuels, improve efficiencies, cut costs, and decrease emission levels results in new technologies being continuously developed.

Some industry associations are also making special voluntary contributions to reduce the consumption of fossil fuels and increase the use of wood-based energy. For instance, the European paper industry aims to achieve an approximately 25% increase in the amount of wood fuel used for on-site heat and power production by 2010, and increase the share of wood in its on-site total primary energy consumption from 49 to 56%.

The development of sustainable wood energy systems remains one of the most critical issues to be addressed by policy makers and community planners. With society giving increasing attention to sustainability issues, in the case of wood energy in both developing and developed countries, economic, environmental, and social issues deserve particular attention. Most of the uses of wood are accounted for by combustion in intermediate or large-scale units outside the forest industries (e.g., in schools, hospitals, barracks, or district heating plants), with minor volumes

going to the production of charcoal. Small volumes were used in a few European countries to generate electricity or to manufacture solid fuels (e.g., briquettes).

Wood is used as a source of energy in a number of forms, and although the generation of electricity from wood is growing, the outlook is less clear for the new types of wood-derived energy that include gaseous fuels (often seen as substitutes or additives to traditional fuels).

Energy Sources

Energy sources are those natural-occurring material that can be used to produce energy. The prime sources of energy have been the various sources known as fossil fuels which are natural gas, crude oil, and coal (Table E-3). Enormous resources of other fossil fuels exist, but they are not yet in large-scale commercial use. Examples of fossil fuels not used currently, but potentially useful in the future, are oil shale and (with the exception of commercialization in Alberta, Canada) tar sand deposits (Table E-3).

Table E-3 General sub-divisions of energy sources.

<i>Conventional Energy Sources</i>
Natural Gas
Crude oil
Heavy Crude Oil
Coal*
<i>Non-conventional Energy Sources</i>
Extra Heavy Crude Oil
Tar sand Bitumen
Coal*
Coal Gas
Coal Liquids
Shale Oil
<i>Renewable Energy Sources</i>
Biomass
Hydrogen
Hydroelectric**
Nuclear
Solar Energy
Ocean Energy**
Tidal Energy**
Wind Energy

*When used as a solid fuel feedstock for combustion (without any modification other than cleaning), coal is often considered to be a conventional energy source.

**Often grouped together under the name “hydrokinetic energy” – hydroelectric energy may also be included in this group.

Over the past 20 to 30 years, the use of older renewable energy sources has increased and there has been a start to the use of new renewable energy sources as well. There has been the realization that fossil fuels and atomic fuels will not last forever, and that the use of these fuel sources and the fuels contributes to environmental pollution.

Renewable energy – which basically comes from the sun in one way or another – provides opportunities for an unlimited, sustainable energy supply with low environmental impact. And renewable energy is not just something for the future, but something that can be used in homes.

True renewable energy sources are energy supplies that are refilled by natural processes at least as fast that can be used. All renewable energy comes, ultimately, from the Sun. The Sun can be used directly (as in solar heating systems) or indirectly (as in hydroelectric power, wind power, and power from biomass fuels). Renewable energy supplies can become exhausted if they are used faster than they become replenished: most of England's forests were cut down for fuel before the English started using coal. If used wisely, however, renewable energy supplies can last forever. There are other alternatives to the typical energy sources that are not renewable. Although these are alternative energy sources rather than renewable energy sources, they use the energy more efficiently than older technologies. In doing this, they help to make the existing energy supplies last longer and give more time before the stored fossil and atomic fuels are completely depleted. Listed below are brief descriptions of these resources.

Biomass

Biomass is second to hydropower as a leader in renewable energy production. Biomass has an existing capacity of over 7,000 MW. Biomass as a fuel consists of organic matter such as industrial waste, agricultural waste, wood, and bark. Biomass can be burned directly in specially designed power plants, or used to replace up to 15% of coal as a fuel in ordinary power plants. Biomass burns cleaner than coal because it has less sulfur, which means less sulfur dioxide will be emitted into the atmosphere. Biomass can also be used indirectly since it produces methane gas as it decays or through a modern process called gasification. Methane can produce power by burning in a boiler to create steam to drive steam turbines or through internal combustion in gas turbines and reciprocating engines. The largest use of biomass energy in Virginia is the forest products industry. Furniture plants, sawmills, and paper mills usually burn their wood waste to produce heat and electricity. Many homeowners use firewood or pellets for winter heat.

Geothermal Energy

Geothermal electric capacity in the United States is over 3,000 MW. Geothermal power plants use high temperatures deep underground to produce steam, which then powers turbines that produce electricity. Geothermal power plants can draw from underground reservoirs of hot water or can heat water by pumping it into hot, dry rock. High underground temperatures are accessed by drilling wells, sometimes more than a mile deep. In one sense, this geothermal energy is not renewable, since sometime in the future the core of the earth will cool. That time is so far off (hundreds of millions of years) that we think of it as renewable. Most geothermal power plants are located in the western United States, but some coastal regions of the eastern United States have geothermal power potential. Geothermal heat pumps use compressors to pump heat out of the earth (for winter heating) or into the earth (when running as air conditioners in summer). The energy they pump into and out of the earth is renewable since it is replaced by the cycle of the seasons. The energy that runs the compressor can either be renewable or conventional.

Hydropower

Hydropower represents one of the oldest and largest renewable powers. Hydropower plants convert the energy of flowing water into electricity. This is primarily done by damming rivers to create large reservoirs and then releasing water through turbines to produce electricity. Hydropower results in no emissions into the atmosphere, but the process of damming a river can create significant ecological problems for water quality and for fish and wildlife habitat.

Solar Energy

Solar energy comes directly from the power of the sun and is used to produce electricity, to produce heat, and for light. Solar represents a small share of the electric market in the United States – approximately one-half of 1% of electrical capacity. Solar's contribution to heating and lighting is much larger. Solar-electric power can be produced, either by power plants using the sun's heat or by photovoltaic (PV) technology, which converts sunlight directly to electricity using solar cells. PV technology is more practical for residential use. Systems to use the heat of the sun

directly can be either active or passive. In active systems, air or liquid circulates through solar collectors and bring heat to where it is used. In passive systems, buildings are built with windows and heat-absorbing surfaces set up to maximize solar heating in winter. Either technology is suitable for residential use. Systems to directly use the light of the sun are most common. The most usual device for using sunlight is the window, but skylights and skylight tubes are also used.

Wind Power

Wind energy represents 4,700 megawatts (MW) of installed electric capacity in the United States. Wind has been the fastest-growing energy source in the U.S. over the last decade mainly due to significant improvements in wind energy technology. The American Wind Energy Association predicts that 6,000 MW of wind power will be installed by the end of 2004. This is enough to power 1.5 million homes. Wind power is produced by the energy of the wind turning aerodynamic blades mounted to a hub. The hub is connected to a shaft that turns a generator. Large utility-scale wind turbines range in size from 50 kilowatts to over four megawatts. Smaller wind towers (under 50 kW) are suitable for residential and agricultural use.

Enersludge Process

The Enersludge process is an alternative to incineration or anaerobic digestion of sewage sludge (or dumping it out at sea, which is still often used as the disposal method which converts the sludge into useful bio-oil).

In essence, this plant uses standard technology, which is fairly common in Europe, to produce dry pellets from the raw sludge. The pellets have a fertilizer and soil conditioning value and are free of pathogens, etc. The innovative part of the Enersludge process is the addition of a pyrolysis unit, which produces gas, char, and oil. The gas and char are used to heat the plant, leaving the bio-oil for revenue-earning activities - either for direct sale or for use on site in an internal combustion engine to produce electricity and offset purchases.

In the process, after being macerated, the raw primary sludge is mixed with active sludge that is in excess when being circulated through the treatment plant so it is taken off and thickened by air diffusion. The blend then leaves the mixer tanks and enters the dewatering centrifuges. Polymers are added to help settle out the solids and results in a sticky cake material. The dilute fraction is separated and returned to the treatment plant and then eventually discharged out to sea.

The alternative option is for the cake to enter the rotary dryer, which is approximately 6 feet in diameter and 20 feet long. An LPG burner is installed as a back-up system for the dryer. The pellets are graded by size using a shaker table - returning the too large and too fine portions for reprocessing through the dryer. The bulk density of the pellets is the quality control measurement, and only after several modifications, including a means of removing hair from the system, was it proved successful.

The Enersludge process converts these pellets into fuel, some of which is used for drying heat. Normally, the pellets are conveyed from the dryer direct to the pyrolysis conversion reactor, although when this is being maintained, up to 50% can be used for fuel in the hot gas generator and the remaining fraction is then sold or dumped. The pyrolysis process involves two stages, with volatiles being driven off at the first stage and the char passing from stage 1 to stage 2. The heavy metals present in the sludge act as catalysts. An LPG burner is installed to maintain the temperature at 400°C. From 1 ton of pellets, around 80 gallons of bio-oil is produced. In the longer term, it is hoped to produce this bio-oil to a sufficient standard in order to provide a portion of the power requirements for the site.

The hot gas generator is a fluidized bed incinerator designed originally for burning coal dust, but scaled down. Ash from the fluidized bed incinerator includes the heavy metals that are now immobilized. This can either be land-filled or used in a concrete mix to make terracotta paving bricks.

Enrichment

The purpose of enrichment is to produce a gas stream for sale and enriched tank oil. The tank oil contains more low-boiling hydrocarbon liquids than natural crude oil, and the residue gas is drier (leaner, i.e., has lesser amounts

of the higher-molecular-weight hydrocarbon derivatives). Therefore, the process concept is essentially the separation of hydrocarbon liquids from the methane to produce a lean, dry gas.

Crude oil enrichment is used when there is no separate market for low-boiling hydrocarbon liquids or when the increase in API gravity of the crude provides a substantial increase in the price per unit volume as well as volume of the stock tank oil. A very convenient method of enrichment involves manipulation of the number and operating pressures of the gas-oil separators (traps). However, it must be recognized that alteration or manipulation of the separator pressure affects the gas compression operation as well as influences other processing steps.

One method of removing light ends involves the use of a pressure reduction (vacuum) system. Generally, stripping of light ends is achieved at low pressure, after which the pressure of the stripped crude oil is elevated so that the oil acts as an absorbent. The crude oil, which becomes enriched by this procedure, is then reduced to atmospheric pressure in stages or using fractionation (rectification).

See also: Gas Cleaning, Gas Processing, Gas Treating.

Entrained-Bed Combustion

In entrained-bed combustion systems, fine grinding and increased retention times intensify combustion but the temperature of the carrier and degree of dispersion are also important. In practice, the coal is introduced at high velocities which may be greater than 100 feet/second and involve expansion from a jet to the combustion chamber. The pulverized coal is usually suspended in a stream of primary air (approximately 25% of the total air requirement), and the remainder of the air for combustion is introduced as secondary air. The secondary air may be introduced at an inlet region surrounding, or adjacent to, the primary air duct. The temperature of the primary air should be regulated within limits; a temperature of at least 60°C (140°F) is required to prevent the condensation of moisture in the lines, but at temperatures of 80 to 130°C (175 to 265°F) bituminous coal particles, for instance, will soften and stick.

See also: Combustion.

Entrained-Bed Gasifier

In the entrained bed (entrained flow) gasifier, a dry pulverized solid, an atomized liquid fuel, or a fuel slurry is gasified with oxygen (much less frequent: air) in co-current flow. The gasification reactions take place in a dense cloud of fine particles. Most coal is suitable for this type of gasifier because of the high operating temperatures and because the coal particles are well separated from one another. The high temperatures and pressures also mean that a higher throughput can be achieved, but thermal efficiency is somewhat lower as the gas must be cooled before it can be cleaned with existing technology. The high temperatures also mean that tar and methane are not present in the product gas; however, the oxygen requirement is higher than for the other types of gasifiers. All entrained flow gasifiers remove the major part of the ash as a slag as the operating temperature is well above the ash fusion temperature. A smaller fraction of the ash is produced either as a fine dry fly ash or as black fly ash slurry. Some fuels, in particular certain types of biomasses, can form slag that is corrosive for ceramic inner walls that serve to protect the gasifier outer wall. However, some entrained bed type of gasifiers do not possess a ceramic inner wall but have an inner water or steam cooled wall covered with partially solidified slag. These types of gasifiers do not suffer from corrosive slag. Some fuels have ashes with a high ash fusion temperature. In this case, mostly limestone is mixed with the fuel prior to gasification. Addition of limestone will usually suffice for lowering the fusion temperatures. The fuel particles must be much smaller than for other types of gasifiers. This means the fuel must be pulverized, which requires somewhat more energy than for the other types of gasifiers. By far, the most energy consumption related to entrained bed gasification is not the milling of the fuel but the production of oxygen used for the gasification.

Thus, in the entrained flow gasifier, a dry pulverized solid, an atomized liquid fuel, or a fuel slurry is gasified with oxygen (much less frequent: air) in co-current flow. The gasification reactions take place in a dense cloud of fine particles. Most coals are suitable for this type of gasifier because of the high operating temperatures and because the coal particles are well separated from one another. The high temperatures and pressures also mean that a higher throughput can be achieved; however, thermal efficiency is somewhat lower as the gas must be cooled before it can

be cleaned with existing technology. The high temperatures also mean that tar and methane are not present in the product gas; however, the oxygen requirement is higher than for the other types of gasifiers. All entrained flow gasifiers remove the major part of the ash as a slag as the operating temperature is well above the ash fusion temperature. A smaller fraction of the ash is produced either as a fine dry fly ash or as a black colored fly ash slurry. Some fuels, in particular certain types of biomasses, can form slag that is corrosive for ceramic inner walls that serve to protect the gasifier outer wall. However, some entrained bed type of gasifiers do not possess a ceramic inner wall but have an inner water or steam cooled wall covered with partially solidified slag.

See also: Entrained-Bed, Gasification, Gasifiers.

Entrained-Flow Process

The process is based on an air-blown, atmospheric pressure, entrained-bed slagging gasifier, and in the process, part of the coal char is charged to the combustion section of the gasifier to supply the heat necessary for the endothermic gasification reaction.

In the combustion section, substantially all of the ash in the system is converted to molten slag, which is removed via the bottom of the gasifier. The remainder of the coal is fed to the reaction section of the gasifier where it is contacted with hot gases entering the reaction zone from the combustor. The gasification process takes place in the entrainment section of the reactor where the coal is devolatilized and reacts with the hot gases to produce the desired product gas.

The gas contains solid particles and hydrogen sulfide; the former are removed and recycled to the combustor by means of a spray drier, cyclone separators, and venturi scrubbers, and the hydrogen sulfide is removed and elemental sulfur produced by the Stretford process.

See also: Entrained-Bed, Entrained-Bed Combustion, Entrained-Bed Reactor.

Entrained Flow Reactor

This type of reactor is also referred to as entrained flow reactor since there is no bed of solids in the most practical sense. This reactor system uses finely pulverized coal particles blown into the gas stream before entry into the reactor, with combustion and gasification occurring inside of the coal particles suspended in the gas phase. Due to the entrainment requirement, high space velocity of gas stream and fine powdery coal particles are very essential to the operation of this type of process. Due to the short residence time (i.e., high space velocity) in the reactor, a high temperature is required to achieve a good conversion in such a short period of reaction time. This can also be assisted by using excess oxygen. This bed configuration is typically capable of handling both caking and non-caking coals without much operational difficulty. Examples of commercial gasifiers that use this type of reactor include Koppers-Totzek gasifier and Texaco gasifier.

See also: Entrained Bed Gasifier.

Environment

The environment is the sum of all external factors (biotic and abiotic) that influence the life of an organism. Biotic factors include all living beings (for example, humans, animals, plants, and microorganisms), whereas abiotic factors include all physico-chemical entities (such as air, water, soil, rocks, minerals, and mountains). The environment can be natural, human engineered, or even abstract (non-material). Owing to such vagueness, the term environment has been used in various ways or in various perspectives. For example, terms such as natural environment, extra-terrestrial environment, human-engineered environment, socio-political-cultural environment, business environment, family environment, and workplace environment are used in general conversation.

The influence of the environment on organisms can be viewed on a large scale (i.e., the relationship between regional climate and geographic distribution of organisms) or on a smaller scale (i.e., some highly localized conditions determine the precise location and activity of individual organisms). For example, an organisms may respond

differently to the frequency and duration of a given environmental change. In addition, if some individual organisms in a population have adaptations which allow them to survive and to reproduce under new environmental conditions, the population will continue but the genetic composition will have changed (Darwinism). On the other hand, some organisms have the ability to adapt to the environment (i.e., to adjust their physiology or morphology in response to the immediate environment) so that the new environmental conditions are less (certainly no more) stressful than the previous conditions. But such changes may not be genetic (Lamarckism).

Environmental Ethics

Environmental ethics involves the study of the moral relationship of human beings with the environment and its non-human contents. This is especially important to scientists and engineers who are working on issues related to maintaining an environment that is as close as possible to a pristine environment. Thus, environmental ethics is the part of environmental philosophy which considers extending the traditional boundaries of ethics from solely including humans to including the nonhuman world. It exerts influence on a large range of disciplines including law, sociology, theology, economics, ecology, and geography. Environmental ethics ensures that humans should base their behavior on a set of ethical values that guide the human approach toward the other living beings in nature. Even if the human race is considered the primary concern of society, plants and animals (flora and fauna) are also important have the right of existence.

The concept of environmental ethics developed into a specific philosophical discipline in the 1970s due to the increasing awareness in the 1960s of the effects that technology, industry, economic expansion, and population growth were having on the environment. However, pollution and the depletion of natural resources have not been the only environmental concerns since that time and issues such as (i) dwindling plant and animal biodiversity, (ii) the loss of wilderness areas, (iii) the degradation of ecosystems, and (iv) climate change are all part of a raft of issues that have implanted themselves into both public consciousness and public policy over subsequent years.

Thus, environmental ethics deals with the issues related to the rights and duties of individuals that are fundamental to the life and well-being of present human society, future generations (of humans), as well as of other living beings present on the Earth. Environmental ethics evolved in the 1970s as a sub-discipline of environmental science and environmental engineering. The subject differs from traditional ethics which is concerned with relationships among humans only. The need of environmental ethics has arisen as a result of the following three major factors: (i) modern technological civilization has been affecting nature greatly; therefore, there is a need to analyze the consequences of human actions, (ii) as a result of the advancement of science, human understanding related to nature and environmental problems is increasing, and (iii) there is a concern – or belief – that other living species have equal rights to live on the Earth is also raising the need for environmental ethics. Therefore, it is necessary to understand and accept that the life-supporting environment of the Earth is the outcome of complex interaction of innumerable physical, chemical, and biological factors. With the advancement in the methods of scientific investigation, the human understanding of these factors is also increasing.

The term conservation ethics is an extension of use-value in _____ to the non-human biological world which focuses only on the worth of the environment in terms of its utility or usefulness to humans. The concept generally advocates preservation of the environment on the basis that it has extrinsic value insofar as it is instrumental to the welfare of human beings. Conservation is therefore a means to an end and purely concerned with mankind and inter-generational considerations.

Conservation ethics is related to anthropocentrism which advocates that humans are the most important or critical element in any given situation; that the human race must always be its own primary concern.

Environmental Issues

There are two areas of environmental concern when considering using biomass as a form of energy. First, there is the issue of land degradation and deforestation – this concern can be addressed by proper management of sustainable

energy crops. Although much of the biomass requirement for energy production can be met through utilizing residues from the food industry, from agriculture, or from commercial activity, careful planning of energy cropping is required to prevent undue stress on the environment.

With the recent global call to reduce carbon dioxide emissions, there is a strong case for promoting the use of sustainable biomass-to-energy technologies worldwide. Using modern technology, enormous reductions can be made in carbon dioxide emissions, particularly if liquid biofuels are used to replace their fossil-based equivalents. In fact, if biomass energy production is done on a sustainable basis, there is little net carbon dioxide addition to the environment. There are other environmental concerns related to each fuel that need to be kept in mind, such as toxic emissions and production of tar and soot.

There is a consensus among scientists that biomass fuels used in a sustainable manner result in no net increase in atmospheric carbon dioxide (CO_2). Some would even go as far as to declare that sustainable use of biomass will result in a net decrease in atmospheric CO_2 . This is based on the assumption that all the CO_2 given off by the use of biomass fuels was recently taken in from the atmosphere by photosynthesis. Increased substitution of fossil fuels with biomass-based fuels would therefore help reduce the potential for global warming, caused by increased atmospheric concentrations of carbon dioxide.

Unfortunately, things may not be as simple as has been assumed above. Currently, biomass is being used all over the world in a very unsustainable manner, and the long-term effects of biomass energy plantations have not been proven. As well, the natural humus and dead organic matter in the forest soils is a large reservoir of carbon. Conversion of natural ecosystems to managed energy plantations could result in a release of carbon from the soil as a result of the accelerated decay of organic matter.

An ever-increasing number of people on this planet are faced with hunger and starvation. It has been argued that the use of land to grow fuel crops will increase this problem. Hunger in developing countries, however, is more complex than just a lack of agricultural land. Many countries in the world today, such as the U.S., have food surpluses. Much fertile agricultural land is also used to grow tobacco, flowers, food for domestic pets, and other "luxury" items, rather than staple foods. Similarly, a significant proportion of agricultural land is used to grow feed for animals to support the highly wasteful, meat-centered diet of the industrialized world. By feeding grain to livestock, the result is approximately 10% of the caloric content of the grain. When looked at in this light, it does not seem to be so unreasonable to use some fertile land to grow fuel. Marginal land and underutilized agricultural land can also be used to grow biomass for fuel.

Acid rain, which can damage lakes and forests, is a by-product of the combustion of fossil fuels, particularly coal and oil. The high sulfur content of these fuels together with hot combustion temperatures result in the formation of sulfur dioxide (SO_2) and nitrous oxides (NO_x) when they are burned to provide energy. The replacement of fossil fuels with biomass can reduce the potential for acid rain. Biomass generally contains less than 0.1% sulfur by weight compared to low sulfur coal with 0.5–4% sulfur. Lower combustion temperatures and pollution control devices such as wet scrubbers and electro-static precipitators can also keep emissions of NO_x to a minimum when biomass is burned to produce energy.

The final major environmental impact of biomass energy may be that of loss of biodiversity. Transforming natural ecosystems into energy plantations with a small number of crops, as few as one, can drastically reduce the biodiversity of a region. Such "monocultures" lack the balance achieved by a diverse ecosystem, and are susceptible to widespread damage by pests or disease.

Biomass is by no means the only solution to global warming and other problems, and the environmental effects of its use should be examined very closely.

For instance, the combustion of wastes solves a disposal problem and may offset the use of fossil fuels but the incombustible materials such as ash have to be removed from the site. This incurs a cost to the environment due to pollution from transportation. In addition, if care is not taken and a conventional combustion chamber is used (as opposed to a newly designed one that is capable of filtering out harmful emissions), by-products such as particulates and poly-aromatic hydrocarbon derivatives (PAHs) can escape to the atmosphere.

On the other hand, tree planting on a large scale (such as the one needed for arable coppicing) helps in the absorption of CO_2 . If care is taken in the overall processing (harvesting, chipping, transporting, drying, and so on) of this biomass feedstock, then the net carbon dioxide emissions after it has been used for fuel will be less than the absorbed carbon dioxide, thus benefiting the environment.

On the other hand, methane is a very harmful greenhouse gas as well as causing accidental explosions due to its migration from landfill sites to nearby buildings. Moreover, it has 30 times the damaging effect on the environment

than that of CO_2 . The extraction, use of, and combustion of methane actually protects against global warming. Even though a by-product of the process is carbon dioxide, the net effect to the environment is much smaller.

Finally, another issue concerning the environment is the use of set-aside land for energy crops. SRC has potential as there are only a few stumbling points that may cause some objections; for example, the potentially sensitive nature of sites has to be considered – proximity to settlements and roads – as views could be impeded due to the growth rates causing a 3-dimensional woodland type mass in the field. But integrating the area with the surrounding landscape – trees and other features – when establishing new plantations can reduce visual impact. Also, changes in the landscape can be quick during growth and also during harvesting.

Additionally, the scale of short rotation coppicing has to be considered to avoid saturation of the landscape by monotonous planting. F farming conforms with regulations related to adjacent plots of different tree species and so, on most of the above concerns, can turn out to be unfounded.

Environmental Issues – Biomass Use

There are two areas of environmental concern when considering using biomass as a form of energy. Firstly, there is the issue of land degradation and deforestation. This concern can be addressed by proper management of sustainable energy crops. Although much of the biomass requirement for energy production can be met through utilizing residues from the food industry, from agriculture, or from commercial activity, careful planning of energy cropping is required to prevent undue stress on the environment.

With the recent global call to reduce carbon dioxide emissions, there is a strong case for promoting the use of sustainable biomass-to-energy technologies worldwide. Using modern technology, enormous reductions can be made in carbon dioxide emissions, particularly if liquid biofuels are used to replace their fossil-based equivalents. In fact, if biomass energy production is done on a sustainable basis, there is little net carbon dioxide addition to the environment.

There are other environmental concerns related to each fuel that need to be kept in mind, such as toxic emissions and production of tar and soot.

There is a consensus among scientists that biomass fuels used in a sustainable manner result in no net increase in atmospheric carbon dioxide (CO_2). Some would even go as far as to declare that sustainable use of biomass will result in a net decrease in atmospheric carbon dioxide. This is based on the assumption that all of the carbon dioxide that is emitted by the use of biomass fuels was recently taken in from the atmosphere by photosynthesis. Increased substitution of fossil fuels with biomass-based fuels would therefore help reduce the potential for global warming, caused by increased atmospheric concentrations of carbon dioxide.

Unfortunately, things may not be as simple as has been assumed above. Currently, biomass is being used all over the world in a very unsustainable manner, and the long-term effects of biomass energy plantations have not been proven. As well, the natural humus and dead organic matter in the forest soils are a large reservoir of carbon. Conversion of natural ecosystems to managed energy plantations could result in a release of carbon from the soil as a result of the accelerated decay of organic matter.

An ever-increasing number of people on this planet are faced with hunger and starvation. It has been argued that the use of land to grow fuel crops will increase this problem. Hunger in developing countries, however, is more complex than just a lack of agricultural land. Many countries in the world have food surpluses. Much fertile agricultural land is also used to grow tobacco, flowers, food for domestic pets, and other “luxury” items, rather than staple foods. Similarly, a significant proportion of agricultural land is used to grow feed for animals to support the highly wasteful, meat-centered diet of the industrialized world. By feeding grain to livestock, there is only approximately 10% of the caloric content of the grain. When looked at in this light, it does not seem to be so unreasonable to use some fertile land to grow fuel. Marginal land and underutilized agricultural land can also be used to grow biomass for fuel.

Acid rain, which can damage lakes and forests, is a by-product of the combustion of fossil fuels, particularly coal and oil. The high sulfur content of these fuels together with hot combustion temperatures result in the formation of sulfur dioxide (SO_2) and oxides of nitrogen (NO_x) when they are burned to provide energy. The replacement of fossil fuels with biomass can reduce the potential for acid rain. Biomass generally contains less than 0.1% sulfur by weight

compared to low sulfur coal with 0.5-4% sulfur. Lower combustion temperatures and pollution control devices such as wet scrubbers and electro-static precipitators can also keep the emissions of oxides of nitrogen to a minimum when biomass is burned to produce energy.

The final major environmental impact of biomass energy may be that of loss of biodiversity. Transforming natural ecosystems into energy plantations with a small number of crops, as few as one, can drastically reduce the biodiversity of a region. Such “monocultures” lack the balance achieved by a diverse ecosystem, and are susceptible to widespread damage by pests or disease.

Biomass is by no means the only solution to global warming and other problems, and the environmental effects of its use should be examined very closely.

For instance, the combustion of wastes solves a disposal problem and may offset the use of fossil fuels, but the incombustible materials such as ash have to be removed from the site. This incurs a cost to the environment due to pollution from transportation. In addition, if care is not taken and a conventional combustion chamber is used (as opposed to a newly designed one that is capable of filtering out harmful emissions), by-products such as particulates and poly-aromatic hydrocarbon derivatives (PAHs, also called polynuclear aromatic hydrocarbon derivatives, PNAs) can escape to the atmosphere.

On the other hand, tree planting on a large scale (such as the one needed for arable coppicing) helps in the absorption of carbon dioxide. If care is taken in the overall processing (harvesting, chipping, transporting, drying, and so on) of this biomass feedstock, then the net carbon dioxide emissions after it has been used for fuel will be less than the absorbed carbon dioxide thus benefiting the environment.

On the other hand, methane is a very harmful greenhouse gas as well as causing accidental explosions due to its migration from landfill sites to nearby buildings. Moreover, it has 30 times the damaging effect on the environment than that of carbon dioxide. The extraction, use of, and combustion of methane actually protects against global warming. Even though a by-product of the process is carbon dioxide, the net effect to the environment is much smaller.

Finally, another issue concerning the environment is the use of set-aside land for energy crops. SRC has potential as there are only a few stumbling points that may cause some objections; for example, the potentially sensitive nature of sites has to be considered – proximity to settlements and roads – as views could be impeded due to the growth rates causing a 3-dimensional woodland-type mass in the field. But integrating the area with the surrounding landscape – trees and other features – when establishing new plantations can reduce visual impact. Also, changes in the landscape can be quick during growth and also during harvesting.

Additionally, the scale of short rotation coppicing has to be considered to avoid saturation of the landscape by monotonous planting. F farming conforms with regulations related to adjacent plots of different tree species and so, on most of the above concerns, can turn out to be unfounded.

Enzymatic Hydrolysis

Enzymatic hydrolysis is a process in which enzymes facilitate the cleavage of bonds in molecules with the addition of the elements of water and plays an important role in the human system for the digestion of food. In the current context, the process involves the addition of cellulases (a group of enzymes which, when acting together, hydrolyze cellulose) to hydrolyze pretreated lignocellulosic biomass into fermentable sugars. The process involves several key steps: (i) transfer of enzymes from the bulk aqueous phase to the surface of the cellulose, (ii) adsorption of the enzymes and formation of enzyme-substrate complexes, (iii) hydrolysis of the cellulose, (iv) transfer of the hydrolysis products from the surface of the cellulosic particles to the bulk aqueous phase, and (v) hydrolysis of the sugar-type products to glucose in the aqueous phase. The overall rate of the process is influenced by the structural features of lignocellulosic biomass and the composition and source of the cellulases.

Thus, the enzymatic hydrolysis process was developed to better utilize both cellulose and hemicellulose from lignocellulosic materials. The enzymatic process must be preceded by extensive pre-treatment to separate cellulose, hemicellulose, and lignin. Because milder conditions are used compared to acid hydrolysis of cellulose, subsequent enzymatic hydrolysis of the cellulose does not degrade pentoses during pre-hydrolysis. Cellulose is a homopolysaccharide of glucose linked by 1,4-glycoside-type bonds (bonds in which a sugar molecule is bound to another functional group, also known as glycosidic bond). Enzymatic hydrolysis of cellulose proceeds in several steps to break

glycoside-type bonds by the action of a system of enzymes known as cellulase. The system of enzymes also contains hemicellulase to hydrolyze any hemicellulose not solubilized by prehydrolysis. Unfortunately, enzymatic technologies are not likely to be suitable for unsorted municipal solid waste due to its high heterogeneity, and further research is necessary to convert wastes that are high in hemicellulose.

In a fermentation process, glucose is fermented to produce a dilute ethanol-water solution (dilute beer). Xylose is difficult to convert to ethanol, but it does occur. Lignin, which is not susceptible to biological transformation, can be chemically upgraded or more frequently, simply burned as boiler fuel.

Simultaneous saccharification and fermentation (SSF) has been developed for fermenting sugars released from lignocellulose. The process combines hydrolysis and fermentation to overcome end product inhibition. By combining hydrolysis and fermentation, glucose is rapidly removed before it can inhibit further hydrolysis. In the process, biomass feedstock is milled and then pre-hydrolyzed to yield a mixture of pentoses (xylose and arabinose) and fiber. The mixture is neutralized with limestone and mixed with cellulase and hemicellulase enzymes. The cellulose and any remaining hemicellulose are solubilized to hexose (glucose) and pentoses (xylose and arabinose), which are immediately fermented to ethanol. The optimum temperature for the hydrolysis-fermentation reaction is between the optimum temperature for cellulase activity and the best temperature for the yeast. Lignin is separated from the mixture and used as boiler fuel or converted to high-value octane enhancers that can be blended with gasoline.

The first application of enzymes to wood hydrolysis in an ethanol process was simply to replace the cellulose acid hydrolysis step with a cellulase enzyme hydrolysis step. This is called separate hydrolysis and fermentation. The most important process improvement made for the enzymatic hydrolysis of biomass was the introduction of simultaneous saccharification and fermentation (SSF) which reduced the number of reactors involved by eliminating the separate hydrolysis reactor and, more importantly, avoiding the problem of product inhibition associated with enzymes.

In the simultaneous saccharification and fermentation process, cellulase enzyme and fermenting microbes are combined. As sugars are produced by the enzymes, the fermentative organisms convert them to ethanol. The SSF process has recently been improved to include the co-fermentation of multiple sugar substrates.

Cellulase enzymes are already commercially available for a variety of applications. Most of these applications do not involve extensive hydrolysis of cellulose. For example, the textile industry applications for cellulases require less than 1% hydrolysis. Ethanol production, by contrast, requires nearly complete hydrolysis. In addition, most of the commercial applications for cellulase enzymes represent higher value markets than the fuel market. For these reasons, there is quite a large leap from the current cellulase enzyme industry to the fuel ethanol industry.

See also: Enzymes.

Enzymes

Enzymes (biocatalysts) are complex protein-based compounds produced by living cells, and they catalyze hydrolysis and oxidation reactions. With the current drive toward production of renewable fuels from plant material, enzymes which can break down this material into useable compounds are required in industrial quantities and at a low cost.

In addition to enhancing the reaction rate, enzymes have the ability to discriminate among competing substrates. Enzyme specificity arises mainly from three sources which are (i) the exclusion of other molecules from the active site because of the presence of incorrect functional groups, or the absence of necessary binding groups, (ii) many weak interactions exist between the substrate and the enzyme, and (iii) stereospecificity arises from the fact that enzymes are built from only L-amino acids and have active sites which are asymmetric and will bind only certain substrates.

Traditional methods of generating enzymes for biofuel production currently operate at over five times the target cost required to make the fuels financially competitive. By using plants which have been engineered to make the proteins, it may be possible to meet this target. One option is to focus on producing cellulase, enzymes which can break down biomass, such as the constituents of maize seed. By carefully designing the processing chain, from a single crop of maize, oil that can be turned into biodiesel can be produced.

Enzyme-based biofuel cells are attracting attention rapidly partially due to the promising advances reported recently. However, there are issues to be addressed before biofuel cells become competitive in practical applications. Two critical issues are short lifetime and poor power density, both of which are related to enzyme stability, electron transfer rate, and enzyme loading.

Enzymatic activity is regulated in four general ways, which are (i) allosteric control, which is due to allosteric enzymes – the enzymes that have distinct binding sites for effector molecules, which control their rates of reaction, (ii) designated control proteins, which participate in cellular regulatory processes, (iii) a mechanism involves the reversible chemical modification that can be carried out with a variety of chemical groups, and (iv) proteolytic activation, which involves activation of enzyme activity that occurs when part of the protein is removed) can regulate the activity of some enzymes. Proteolytic enzymes are controlled by this latter mechanism.

Also, enzyme inhibitors diminish the activity of an enzyme by altering the way substrates bind to the enzyme. The structure of the inhibitor may be similar to the substrate – chemically, an inhibitor may be a large organic molecule, or a small molecules, or an ion. Inhibitors work in either a reversible or an irreversible manner. Irreversible inhibition is characterized by interaction of the inhibitor with the enzyme, resulting in slow dissociation and inactivation. There are three main classes of reversible inhibition, which are (i) competitive inhibition, (ii) noncompetitive inhibition, and (iii) mixed inhibition which are distinguishable by the manner in which the inhibitor binds to the enzyme and the response to increasing substrate concentration.

Recent progress in nano-biocatalysis opens the possibility to improve in these aspects. Many nano-structured materials, such as mesoporous media, nanoparticles, nanofibers, and nanotubes, have been demonstrated as efficient hosts of enzyme immobilization. It is evident that, when nanostructure of conductive materials are used, the large surface area of these nanomaterials can increase the enzyme loading and facilitate reaction kinetics, and thus improving the power density of biofuel cells. In addition, research efforts have also been made to improve the activity and stability of immobilized enzymes by using nanostructures. It appears to be reasonable to expect that progress in nanostructured biocatalysts will play a critical role in overcoming the major obstacles in the development of powerful biofuel cells.

Esterification

Biodiesel can be produced from straight vegetable oil, animal oil/fats, tallow, and waste oils. There are three basic routes to biodiesel production from oils and fats: (i) base-catalyzed transesterification of the oil, (ii) direct acid-catalyzed transesterification of the oil, and (iii) conversion of the oil to its fatty acids and then to biodiesel.

Almost all biodiesel is produced using base-catalyzed transesterification as this is the most economical process. It requires only low temperatures and pressures and produces a 98% conversion yield. The transesterification process is the reaction of a triglyceride (fat/oil) with an alcohol to form esters and glycerol. A triglyceride has a glycerine molecule as its base with three long-chain fatty acids attached. The characteristics of the fat are determined by the nature of the fatty acids attached to the glycerine. During the esterification process, the triglyceride is reacted with alcohol in the presence of a catalyst, usually a strong alkaline like sodium hydroxide. The alcohol reacts with the fatty acids to form the mono-alkyl ester, or biodiesel, and crude glycerol. In most cases, methanol or ethanol is the alcohol used, where methanol produces methyl esters, and ethanol produces ethyl esters. Potassium hydroxide has been found to be more suitable for the ethyl ester biodiesel production. Either base catalyst can be used for the methyl ester. A common product of the transesterification process is rape methyl ester (RME) produced from raw rapeseed oil reacted with methanol.

The reaction between the fat or oil and the alcohol is a reversible reaction so that alcohol must be added in excess to drive the reaction toward the right and ensure complete conversion. The products of the reaction are the biodiesel itself and glycerol. Put simply, the equation is:

A successful transesterification reaction is signified by the separation of the ester and glycerol layers after the reaction time. The heavier co-product, glycerol, settles out and may be sold as it is, or it may be purified for use in other industries, e.g., the pharmaceutical, cosmetics industries. Biodiesel is a less toxic and more biodegradable fuel than is crude oil diesel and is often blended with crude oil diesel to provide a renewable energy component in the fuel.

Ethanol

Ethanol (ethyl alcohol, alcohol, grain-spirit; C_2H_5OH) is a clear, colorless, flammable oxygenated hydrocarbon.

Ethanol (Table E-4) is a volatile, flammable, colorless liquid that has a strong characteristic odor. It burns with a smokeless blue flame that is not always visible in normal light. The physical properties of ethanol stem primarily from the presence of the hydroxyl group and the shortness of its carbon chain. The hydroxyl group is able to participate in hydrogen bonding, rendering it more viscous and less volatile than less polar organic compounds of similar molecular weight.

Table E-4 Selected properties of ethanol compared to methanol.

Property	Ethanol	Methanol
Formula	C_2H_5OH	CH_3OH
Appearance	Colorless liquid	Colorless liquid
Molecular formula	C_2H_6O	CH_4O
Molecular weight	46	32
Specific gravity	0.788 (25°C)	0.789 ((25°C)
Vapor density relative to air	1.59	1.10
Liquid density ($g\ cm^{-3}$ at 25°C)	0.79	0.79
Boiling point (°C)	78	65
Melting point (°C)	-144	-98
Vapor pressure @ 100°C (psia)	2.5	4.6
Heat of evaporation (Btu/lb)	410	472
Heating value (kBTU gallon ⁻¹)		
Lower (LHV)	74	58
Upper (UHV)	85	65
Tank design pressure (psig)	15	15
Viscosity (cp)	1.20	0.54
Flash point (K)	287	284
Flammability/explosion limits		
- (%) Lower (LFL)	3.3	6.7
- (%) Upper (UFL)	19	36
Auto ignition temperature (K)	636	733
Solubility in water (%)	Miscible (100%)	Miscible(100%)
Azeotrope with water	95% v/v EtOH	None

Ethanol is used as a vehicle fuel by itself (E100 is 100% ethanol by volume), blended with gasoline (E85 is 85% ethanol by volume), or as a gasoline octane enhancer and oxygenate (10% by volume).

Ethanol is produced both as a petrochemical, through the hydration of ethylene, and biologically, by fermenting sugars with yeast. Ethanol for use as industrial feedstock is most often made from petrochemical feed stocks, typically by the acid-catalyzed hydration of ethylene:

The catalyst is most commonly phosphoric acid, adsorbed onto a porous support such as diatomaceous earth or charcoal. The reaction is carried out with an excess of high pressure steam at 300°C (570°F).

Ethanol is miscible with water and with many organic solvents, including acetic acid, acetone, benzene, carbon tetrachloride, chloroform, diethyl ether, ethylene glycol, glycerol, nitromethane, pyridine, and toluene. It is also miscible with low-boiling aliphatic hydrocarbon derivatives, such as pentane and hexane, and with aliphatic chlorides such as trichloroethane and tetrachloroethylene. The miscibility of ethanol with water contrasts with that of longer-chain alcohols (five or more carbon atoms), whose water miscibility decreases sharply as the number of carbons increases.

Hydrogen bonding causes pure ethanol to be hygroscopic to the extent that it readily absorbs water from the air. The polar nature of the hydroxyl group causes ethanol to dissolve many ionic compounds, notably sodium and potassium hydroxides, magnesium chloride, calcium chloride, ammonium chloride, ammonium bromide, and sodium bromide. Sodium and potassium chlorides are slightly soluble in ethanol. Because the ethanol molecule also has a nonpolar end, it will also dissolve nonpolar substances, including most essential oils and numerous flavoring, coloring, and medicinal agents.

Ethanol-water mixtures have less volume than the sum of their individual components – for example, mixing equal volumes of ethanol and water results in only 1.92 volumes of mixture. The addition of even a few percent of ethanol to water sharply reduces the surface tension of water. This property partially explains the tears of wine phenomenon. When wine is swirled in a glass, ethanol evaporates quickly from the thin film of wine on the wall of the glass. As the ethanol content of the wine decreases, the surface tension increases and the thin film forms beads and runs down the glass in channels rather than as a smooth sheet.

Mixtures of ethanol and water that contain more than approximately 50% ethanol are flammable and easily ignited. An alcohol stove has been developed in India which runs on 50% ethanol/water mixture. Alcoholic proof is a widely used measure of how much ethanol (i.e., alcohol) such a mixture contains. In the 18th century, proof was determined by adding liquor (such as rum) to gunpowder. If the gunpowder still just exploded, that was considered to be 100 degrees proof that it was good liquor; hence, it was called 100 degrees proof.

Ethanol-water solutions that contain less than 50% ethanol may also be flammable if the solution is first heated. Some cooking methods call for wine to be added to a hot pan, causing it to flash boil into a vapor, which is then ignited to burn off excess alcohol. Ethanol is slightly more refractive than water, having a refractive index of 1.36242 (at $\lambda = 589.3$ nm and 18.35 °C).

Ethanol is classified as a primary alcohol, meaning that the carbon to which its hydroxyl group is attached has at least two hydrogen atoms attached to it as well and the chemistry of ethanol is largely that of the hydroxyl group.

Ethanol can be quantitatively converted to its conjugate base, the ethoxide ion ($\text{CH}_3\text{CH}_2\text{O}^-$), by reaction with an alkali metal such as sodium:

Or a strong base such as sodium hydride:

This reaction is not possible in an aqueous solution, as water is more acidic, so that hydroxide is preferred over ethoxide formation.

Ethanol reacts with hydrogen halides to produce ethyl halides such as ethyl chloride and ethyl bromide:

Reaction with hydrogen chloride requires a catalyst such as zinc chloride. Hydrogen chloride in the presence of their respective zinc chloride is known as Lucas reagent.

Hydrogen bromide requires refluxing with a sulfuric acid catalyst.

Ethyl halides can also be produced by reacting ethanol with more specialized halogenating agents, such as thionyl chloride for preparing ethyl chloride, or phosphorus tribromide for preparing ethyl bromide.

Under acid-catalyzed conditions, ethanol reacts with carboxylic acids to produce ethyl esters and water:

For this reaction to produce useful yields, it is necessary to remove water from the reaction mixture as it is formed.

Strong acid desiccants, such as sulfuric acid, cause the dehydration of ethanol to form either diethyl ether or ethylene:

The actual product, diethyl ether or ethylene, predominates depends on the precise reaction conditions.

Ethanol can be oxidized to acetaldehyde, and further oxidized to acetic acid. In the human body, these oxidation reactions are catalyzed by enzymes.

When exposed to chlorine, ethanol is both oxidized and its alpha carbon chlorinated to form the compound, chloral.

Combustion of ethanol forms carbon dioxide and water:

Ethanol Production

Ethanol is produced from the fermentation of sugar by enzymes produced from specific varieties of yeast. The five major sugars are the five-carbon xylose and arabinose and the six-carbon glucose, galactose, and mannose. Traditional fermentation processes rely on yeasts that convert six-carbon sugars to ethanol. Glucose, the preferred form of sugar for fermentation, is contained in both carbohydrates and cellulose. Because carbohydrates are easier

than cellulose to convert to glucose, the majority of ethanol currently produced in the United States is made from corn, which produces large quantities of carbohydrates. Also, the organisms and enzymes for carbohydrate conversion and glucose fermentation on a commercial scale are readily available.

The conversion of cellulosic biomass to ethanol parallels the corn conversion process. The cellulose must first be converted to sugars by hydrolysis and then fermented to produce ethanol. Cellulosic feedstocks (composed of cellulose and hemicellulose) are more difficult to convert to sugar than are carbohydrates. Two common methods for converting cellulose to sugar are dilute acid hydrolysis and concentrated acid hydrolysis, both of which use sulfuric acid.

Dilute acid hydrolysis occurs in two stages to take advantage of the differences between hemicellulose and cellulose. The first stage is performed at low temperature to maximize the yield from the hemicellulose, and the second, higher temperature stage, is optimized for hydrolysis of the cellulose portion of the feedstock. Concentrated acid hydrolysis uses a dilute acid pretreatment to separate the hemicellulose and cellulose. The biomass is then dried before the addition of the concentrated sulfuric acid. Water is added to dilute the acid and then heated to release the sugars, producing a gel that can be separated from residual solids. Column chromatographic is used to separate the acid from the sugars.

Both the dilute and concentrated acid processes have several drawbacks. Dilute acid hydrolysis of cellulose tends to yield a large amount of by-products. Concentrated acid hydrolysis forms fewer by-products, but for economic reasons, the acid must be recycled. The separation and concentration of the sulfuric acid adds more complexity to the process. The concentrated and dilute sulfuric acid processes are performed at high temperatures (100 and 220°C, 212 to 430°F) which can degrade the sugars, reducing the carbon source and ultimately lowering the ethanol yield. Thus, the concentrated acid process has a smaller potential for cost reductions from process improvements such as acid recovery, and sugar yield for the concentrated acid process could provide higher efficiency for both technologies.

Another approach involves countercurrent hydrolysis, a two-stage process. In the first stage, cellulose feedstock is introduced to a horizontal co-current reactor with a conveyor. Steam is added to raise the temperature to 180°C (no acid is added at this point). After a residence time of approximately 8 minutes, during which some 60% of the hemicellulose is hydrolyzed, the feed exits the reactor. It then enters the second stage through a vertical reactor operated at 225°C (435°F). Very dilute sulfuric acid is added to the feed at this stage, where virtually all of the remaining hemicellulose and, depending on the residence time, anywhere from 60% to all of the cellulose is hydrolyzed. The countercurrent hydrolysis process offers higher efficiency (and, therefore, cost reductions) than the dilute sulfuric acid process. This process may allow an increase in glucose yields to 84%, an increase in fermentation temperature to 55°C (130°F), and an increase in fermentation yield of ethanol to 95%.

The greatest potential for ethanol production from biomass, however, lies in enzymatic hydrolysis of cellulose. The enzyme cellulase, now used in the textile industry to stone wash denim and in detergents, simply replaces the sulfuric acid in the hydrolysis step. The cellulase can be used at lower temperatures, 30 to 50°C, which reduces the degradation of the sugar. In addition, process improvements now allow simultaneous saccharification and fermentation (SSF). In the saccharification and fermentation process, cellulase and fermenting yeast are combined, so that as sugars are produced, the fermentative organisms convert them to ethanol in the same step.

Once the hydrolysis of the cellulose is achieved, the resulting sugars must be fermented to produce ethanol. In addition to glucose, hydrolysis produces other six-carbon sugars from cellulose and five-carbon sugars from hemicellulose that are not readily fermented to ethanol by naturally occurring organisms. They can be converted to ethanol by genetically engineered yeasts that are currently available, but the ethanol yields are not sufficient to make the process economically attractive. It also remains to be seen whether the yeasts can be made hardy enough for production of ethanol on a commercial scale.

Ethanol Production – Feedstocks

A large variety of feedstocks is currently available for producing ethanol from cellulosic biomass. The materials being considered can be categorized as agricultural waste, forest residue, and energy crops. Agricultural waste available for ethanol conversion includes crop residues such as wheat straw, corn stover (leaves, stalks, and cobs), rice straw,

and bagasse (sugar cane waste). Forestry waste includes underutilized wood and logging residues; rough, rotten, and salvable dead wood; and excess saplings and small trees. Energy crops, developed and grown specifically for fuel, include fast-growing trees, shrubs, and grasses such as hybrid poplars, willows, and switchgrass.

Although the choice of feedstock for ethanol conversion is largely a cost issue, feedstock selection has also focused on environmental issues. Materials normally targeted for disposal include forest thinnings collected as part of an effort to improve forest health, and certain agricultural residues, such as rice straw. Although forest residues are not large in volume, they represent an opportunity to decrease the fire hazard associated with the dead wood present in many forests. Small quantities of forest thinnings can be collected at relatively low cost, but collection costs rise rapidly as quantities increase.

Agricultural residues, in particular corn stover, represent a tremendous resource base for biomass ethanol production. Agricultural residues, in the long term, would be the sources of biomass that could support substantial growth of the ethanol industry. At conversion yields of around 60 to 100 gallons per dry ton, the available corn stover inventory would be sufficient to support 7 to 12 billion gallons of ethanol production per year.

The cost of agricultural residues is not nearly as sensitive to supply as is the cost of forest residues, although the availability of corn stover could be affected by a poor crop year. The relatively low rise in cost as a function of feedstock use is due to the relatively high density of material available that does not involve competition for farmland. In addition, the feedstock is located in the corn-processing belt, an area that has an established infrastructure for collecting and transporting agricultural materials. It is also located near existing grain ethanol plants, which could be expanded to produce ethanol from stover. Initially, locally available labor and residue collection equipment might have to be supplemented with labor and equipment brought in from other locations for residue harvesting and storage operations if the plants involved are of sufficient scale. Eventually, however, when the local collection infrastructure has been built up, costs would come down.

Dedicated energy crops such as switchgrass, hybrid willow, and hybrid poplar are another long-term feedstock option. Switchgrass is grown on a 10-year crop rotation basis, and harvest can begin in year 1 in some locations and year 2 in others. Willows require a 22-year rotation, with the first harvest in year 4 and subsequent harvests every 3 years thereafter. Hybrid poplar requires 6 years to reach harvest age in the Pacific Northwest, 8 years in the Southeast, Southern Plains, and South Central regions, and 10 years in the Corn Belt, Lake States, Northeast, and Northern Plains regions. Thus, if it were planted in the spring of 2000, switchgrass could be harvested in 2000 or 2001, willow could be harvested in 2004, and poplars could be harvested in 2006, 2008, or 2010, depending on the region.

The use of cellulosic biomass in the production of ethanol also has environmental benefits. Converting cellulose to ethanol increases the net energy balance of ethanol compared to converting corn to ethanol. The net energy balance is calculated by subtracting the energy required to produce a gallon of ethanol from the energy contained in a gallon of ethanol (approximately 76,000 Btu). Corn-based ethanol has a net energy balance of 20,000 to 25,000 Btu per gallon, whereas cellulosic ethanol has a net energy balance of more than 60,000 Btu per gallon. In addition, cellulosic ethanol use can reduce greenhouse gas emissions. Cellulosic ethanol can produce an 8 to 10% reduction in greenhouse gas emissions when used in E10 and a 68 to 91% reduction when used in E85.

Ethanol Production – From Corn

The production of ethanol from corn is a mature technology that holds much potential. Substantial cost reductions may be possible, however, if cellulose-based feedstocks are used instead of corn.

Producers are experimenting with units equipped to convert cellulose-based feedstocks, using sulfuric acid to break down cellulose and hemicellulose into fermentable sugar. Although the process is expensive at present, advances in biotechnology could decrease conversion costs substantially. The feed for all ethanol fermentations is sugar - traditionally a hexose sugar (a six-carbon sugar or C6 sugar) such as those present naturally in sugar cane, sugar beet, and molasses. Sugar for fermentation can also be recovered from starch, which is actually a polymer of hexose sugars (polysaccharide).

Biomass, in the form of wood and agricultural residues such as wheat straw, is viewed as a low-cost renewable feed to sugar and starch. It is also potentially available in far greater quantities than sugar and starch feeds. As such, it receives significant attention as a feed material for ethanol production. Like starch, wood and agricultural residues

contain polysaccharides. However, unlike starch, while the cellulose fraction of biomass is principally a polymer of easily fermented C6 sugars, the hemicellulose fraction is principally a polymer of C5 sugars; with quite different characteristics for recovery and fermentation, the cellulose and hemicellulose in biomass are bound together in a complex framework of crystalline organic material known as lignin.

These differences mean that recovery of these biomass sugars is more complex than recovery of sugars from a starch feed. Once recovered, fermentation is also more complex than a simple fermentation of C6 sugars. The current focus focuses on the issues of releasing the sugars (hydrolysis) and then fermenting as much of the C6 and C5 sugars as possible to produce ethanol.

There are several different methods of hydrolysis such as (i) concentrated sulfuric acid, (ii) dilute sulfuric acid, and (iii) nitric acid, and acid pretreatment followed by enzymatic hydrolysis.

Ethanol Production – From Lignocellulosic Feedstocks

The production of ethanol from lignocellulosic biomass such as agricultural and forestry residues, municipal solid waste, and energy crops could improve energy security, reduce trade deficits, decrease urban air pollution, and contribute little, if any, net carbon dioxide accumulation to the atmosphere.

Dilute acid can open up the biomass structure for subsequent processing. The simultaneous saccharification and fermentation (SSF) process is favored for producing ethanol from the major fraction of lignocellulosic biomass, cellulose, because of its low- cost potential. Technology has also been developed for converting the second largest biomass fraction, hemicellulose, into ethanol. The remaining fraction, containing mostly lignin, can be burned as boiler fuel to power the conversion process and generate extra electricity to export.

The production of ethanol from lignocellulosic biomass can be achieved through two different processing routes. They are (i) the biochemical route in which enzymes and other micro-organisms are used to convert cellulose and hemicellulose components of the feedstocks to sugars prior to their fermentation to produce ethanol, and (ii) the thermochemical route in which pyrolysis/gasification technologies produce a synthesis gas ($\text{CO} + \text{H}_2$) from which a wide range of long carbon chain biofuels, such as synthetic diesel or aviation fuel, can be reformed. Lignocellulosic biomass consists mainly of lignin and the polysaccharides cellulose and hemicellulose. Compared with the production of ethanol from first-generation feedstocks, the use of lignocellulosic biomass is more complicated because the polysaccharides are more stable and the pentose sugars are not readily fermentable by *Saccharomyces cerevisiae*. As another example, lignocellulose can be converted to ethanol by the hydrolysis route (Figure E-2):

Figure E-2 Ethanol production for lignocellulosic biomass.

However, the conversion efficiency as well as ethanol yield of the biomass differs greatly with respect to the source and nature of the lignocellulosic biomass, primarily due to the variation in lignocellulosic content. Two major polysaccharides in lignocellulosic biomass, namely, cellulose and hemicellulose, firmly link to lignin and form a complex lignocellulosic network, which is highly robust and recalcitrant to depolymerization. For this reason, generation of ethanol from lignocellulosic biomass requires a complicated conversion process that has made it commercially non-competitive. As attempts to exploit lignocellulosic biomass into commercial ethanol production, recent research efforts have been devoted to the techno-economic improvements of the overall conversion process, in addition to screen out promising feedstocks.

Ethanol Production – From Wood

Ethanol produced from various lignocellulosic materials such as wood, agricultural and forest residues has the potential to be a valuable substitute for, or complement to, gasoline.

Ethanol can be produced from lignocellulosic materials in various ways. All processes comprise the same main components: hydrolysis of the hemicellulose and the cellulose to monomer sugars, fermentation and product recovery, and concentration by distillation. The main difference between the process alternatives is the hydrolysis steps, which can be performed by dilute acid, concentrated acid, or enzymatically. Some of the process steps are more or less the same, independent of the hydrolysis method used. For example, enzyme production will be omitted in an acid-hydrolysis process; likewise, the recovery of acid is not necessary in an enzyme-hydrolysis process.

Acid hydrolysis can be performed with several types of acids, including sulfurous, sulphuric, hydrochloric, hydrofluoric, phosphoric, nitric, and formic acid. These acids may be either concentrated or diluted. Processes involving concentrated acids are operated at low temperature and give high yields (e.g., 90% of theoretical glucose yield), but the large amount of acids used causes problems associated with equipment corrosion and energy-demanding acid recovery. Furthermore, when sulphuric acid is used, the neutralization process produces large amounts of gypsum (calcium sulfate, CaSO_4).

The main advantage of dilute acid hydrolysis is the relatively low acid consumption. However, high temperatures are required to achieve acceptable rates of conversion of cellulose to glucose, and high temperatures also increase the rates of hemicellulose sugar decomposition and equipment corrosion. Sugar degradation products can also cause inhibition in the subsequent fermentation stage. The maximum yield of glucose is obtained at high temperature and short residence time, but even under these conditions, the glucose yield is only between 50% and 60% of the theoretical value.

A two-stage process has been developed to decrease sugar degradation. In the first hydrolysis stage, the relatively easily hydrolyzed hemicellulose is released under rather mild conditions. This enables the second acid hydrolysis step to proceed under harsher conditions without degrading the hemicellulose sugars to furfural, hydroxymethyl furfural, and other degradation products.

Ethanol Production - Yields

The variations in organic composition of biomass require thorough consideration to obtain high product yields from a microbial conversion process. In fermentation processes, the lignocellulosic complex is naturally resistant to hydrolysis, so woody and herbaceous biomass often requires significant preparation and pre-treatment. During pre-treatment, weak acids may be used to dissolve and hydrolyze the hemicellulose, leaving a solid residue of cellulose and lignin. Next, the cellulose may be separated and reduced through enzymatic hydrolysis, leaving behind the insoluble lignin. The lignin may then be removed, dried, and burned to provide heat for the process. After the cellulose and hemicellulose are hydrolyzed to simple sugars, microbial conversion uses yeast or bacteria to ferment the sugars, converting them to ethanol, methane, and/or other chemicals.

Cellulose and hemicellulose are composed of different types of sugars that possess different chemical properties. For example, the primary sugar component of cellulose is glucose, a type of hexosan (a polysaccharide yielding only hexose sugar derivatives on hydrolysis). Hemicellulose is primarily xylose, which is a type of pentosan (any

of various polysaccharides that yield only 5-carbon sugar derivatives on hydrolysis). As a result, the cellulose and hemicellulose must be extracted and hydrolyzed through separate processes. Furthermore, different microbes specialize in fermenting specific sugars, so different fermentative organisms are often needed to convert the hexosan derivatives and pentosan derivatives into fuel to achieve a high product yield. Hydrolysis of the holocellulose (the collective term for cellulose and hemicellulose) also produces varying amounts of mannose, galactose, and arabinose sugars, depending on the types of plants in the feedstock.

Sugars require specific enzymes to convert each of them into ethanol and other products. To maximize product yield from a microbial conversion process, it is important to analyze the sugar composition of the feedstock and tailor the enzymes used in the conversion process to optimize fermentation of the specific sugar constituents according to their relative proportions.

Certain microbes can rapidly generate high product yields from xylose and glucose, the primary sugar constituents in commonly available biomass feedstocks. Most fermentative organisms specialize in digesting particular sugars, and few produce the enzymes needed to directly ferment xylose or arabinose. Recently, several strains of yeast and bacteria have been genetically engineered to digest the sugar components of both cellulose and hemicellulose.

Yeast tends to be a very robust organism in ethanol conversion processes, but bacteria, which have the potential to be more efficient, are more susceptible to weak acids and other feed stream toxins such as chemical extractives. Softwoods evolved higher levels of gums and resins that inhibit fungal or bacterial growth. As a result, softwoods and hardwoods usually require distinct enzymatic or microbial conversion processes for optimal yields.

In the conversion of cellulose to ethanol, the approximate ethanol yield per ton of feedstock is a function of three variables: the weight fraction of holocellulose in the feedstock, the fraction of cellulose in the total carbohydrates, and the fraction of total carbohydrates converted to ethanol.

For example, if the feedstock contains 70% holocellulose, of which 80% is converted to ethanol, then the estimated yield is approximately 95 gallons per ton. The fraction of cellulose in the total carbohydrates tends to have a minor effect on ethanol yield in this process. Lignin is insoluble and is left behind as a solid residue after chemical and microbial conversion. The lignin is not easily reduced or fermented and is sometimes wasted, but it has similar heat content to low-grade coal (approximately 10,000-12,000 Btu/lb) and may be dried and burned as fuel in cogeneration systems.

Assuming that most of the remaining 30% of the feedstock in the above example is lignin, enough material can be burned to provide the heat and electricity to power the entire conversion process, as well as excess electricity that can be sold for additional revenue.

Ethyl Alcohol

Evaporation

Evaporation is the process by which molecules in a liquid state spontaneously become gaseous and is the opposite of condensation. Generally, evaporation can be seen by the gradual disappearance of a liquid when exposed to a significant volume of gas. Typically, the molecules do not have enough energy to escape from the liquid, or else the liquid would turn into vapor quickly. When the molecules collide, they transfer energy to each other in varying degrees, based on how they collide. Sometimes, the transfer is so one-sided for a molecule near the surface that it ends up with enough energy to escape.

Evaporation is the opposite of condensation and sublimation and is the phenomenon that occurs when a liquid is transformed to gas without chemical alteration and the conversion of the solid to a liquid and thence the liquid to a gas. Evaporation (the conversion of a liquid to a gas) which is one of several phase transformations that can occur after a chemical is released into the environment (Table E-5) should not be confused with sublimation in which a solid is transferred directly to a gas:

Evaporation:

Liquid → gas

Sublimation:

Solid → gas

Table E-5 Examples of phase transformations.

From	To	Process
Gas	Gas	N/A*
Gas	Liquid	Condensation
Gas	Solid	Deposition
Liquid	Gas	Evaporation or boiling
Liquid	Liquid	N/A*
Liquid	Solid	Freezing
Solid	Gas	Sublimation
Solid	Liquid	Melting
Solid	Solid	Transformation**

*May involve a chemical change depending upon the temperature and pressure

** For example, a change in crystal structure

Both phenomena are important parts of the environmental chemical cycle since both processes involve the disappearance of a contaminant in the water or on the land *but* the contaminant does appear in the atmosphere. Of the two processes, the evaporation is the most common process since chemicals that go through the sublimation processes are not as obvious or as common as chemicals that evaporate. In the field of environmental chemistry, evaporation is more typical when water evaporated from an aqueous solution of the chemical rather than evaporation (volatilization) of the chemical.

Liquids that do not evaporate visibly at a given temperature in a given gas (e.g., cooking oil at room temperature) have molecules that do not tend to transfer energy to each other in a pattern sufficient to frequently give a molecule the heat energy necessary to turn into vapor.

If evaporation takes place in a closed vessel, the escaping molecules accumulate as a vapor above the liquid. Many of the molecules return to the liquid, with returning molecules becoming more frequent as the density and pressure of the vapor increases. When the process of escape and return reaches an equilibrium, the vapor is *saturated*, and no further change in either vapor pressure and density or liquid temperature will occur. For a system consisting of vapor and liquid of a pure substance, the equilibrium state is related to the vapor pressure of the substance (Clausius-Clapeyron equation):

$$\ln\left(\frac{P_2}{P_1}\right) = -\frac{\Delta H_{\text{vap}}}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

P_1 and P_2 are the vapor pressures at temperatures T_1 and T_2 , respectively, ΔH_{vap} is the enthalpy of vaporization, and R is the universal gas constant.

The ability for a molecule of a liquid to evaporate is largely based on the amount of kinetic energy an individual particle may possess. Even at lower temperatures, individual molecules of a liquid can evaporate if they have more than the minimum amount of kinetic energy required for vaporization. The factors which influence the rate of evaporation are: (i) the concentration of the substance evaporating in the air – if the air already has a high concentration of the substance evaporating, then the given substance will evaporate more slowly, (ii) the concentration of other

substances in the air – if the air is already saturated with other substances, it can have a lower capacity for the substance evaporating, (iii) the concentration of other substances in the liquid (impurities) – if the liquid contains other substances, it will have a lower capacity for evaporation, (iv) the flow rate of air – if fresh air is moving over the substance all the time, then the concentration of the substance in the air is less likely to increase with time, thus encouraging faster evaporation, (v) the inter-molecular forces – the stronger the forces keeping the molecules together in the liquid state, the more energy one must get to escape, (vi) the pressure – in an area of less pressure, evaporation happens faster because there is less exertion on the surface keeping the molecules from launching themselves, (vii) the surface area – a substance which has a larger surface area will evaporate faster as there are more surface molecules which are able to escape, (viii) the temperature – if the liquid is hotter, evaporation is more rapid, and (ix) the density – the higher the density, the slower a liquid evaporates.

However, many factors affect the evaporation process. For example, if the air is already saturated with other chemicals (or the humidity is high when the water content is high), there is typically little chance of a liquid evaporating as quickly as when the air is not saturated (or humidity is low). In addition, the air pressure also affects the evaporation process since, under high air pressure, a chemical is much more difficult to evaporate. Temperature also affects the ability of a chemical to evaporate.

See also: Distillation, Evaporation Processes.

Evaporation Processes

Evaporation processes are the final steps for concentrating solid residues. It is generally accomplished in evaporation basins, which are simply lined ponds into which the sludge is pumped and allowed to stand while the moisture evaporates, or in sludge drying beds, which contain a layer of coarse sand over a layer of fine sand over clay or perforated plastic drainage tiles. Both systems require large areas of land compared to other more compact devices such as vacuum filtration, but they are inexpensive and require little maintenance. Sludge drying beds are faster but more expensive. Both systems require mechanical removal of the dried sludge, usually with a backhoe or front-loader.

Falling film vertical tube evaporators have the highest heat transfer characteristics of all evaporator types. A high heat transfer coefficient is needed to efficiently evaporate the water and save energy. The vertical tube, falling film arrangement, also allows evaporation to occur with reduced fouling effects by keeping surfaces wetted at all times. Distributors are used to ensure an even falling film in these evaporators. Zero liquid discharge, if required, is attainable with the evaporative produced water treatment approach.

Exosphere

The exosphere is the outermost layer of the atmosphere (that is, it is the upper limit of the atmosphere) and extends from the exobase, which is located at the top of the thermosphere. The exosphere begins variously from approximately 2,300,000 ft to 3,280,000 ft above the surface, where it interacts with the magnetosphere, to space. Each of the layers has a different lapse rate, defining the rate of change in temperature with height. Initial atmospheric composition is generally related to the chemistry and temperature of the local solar nebula during planetary formation and the subsequent escape of interior gases. The exosphere is an atmosphere so thin that its few atoms or molecules are unlikely to collide with one another. In the atmosphere of the Earth, the exosphere is the highest part of the atmosphere where the density of gas molecules is low.

The exosphere layer is mainly composed of extremely low densities of hydrogen, helium, and several heavier molecules including nitrogen, oxygen, and carbon dioxide closer to the exobase. The atoms and molecules are so far apart that they can travel hundreds of kilometers without colliding with one another. Thus, the exosphere no longer behaves like a gas, and the particles constantly escape into space. The exosphere contains most of the satellites orbiting Earth.

The highly attenuated gas in this layer can reach a temperature on the order of 2,500°C (4,530°F) during the day. Despite the high temperature, an observer or object will experience cold temperatures in the thermosphere, because

the extremely low density of gas (practically a high vacuum) is insufficient for the molecules to conduct heat. In the anacoustic zone (above 99 miles), the density is so low that molecular interactions are too infrequent to permit the transmission of sound.

See also: Atmosphere.

Exothermic Reaction

An exothermic reaction is a chemical reaction process in which heat is evolved. Combustion or burning of a fuel is a complex sequence of exothermic chemical reactions between a fuel (usually a hydrocarbon) and an oxidant accompanied by the production of heat or both heat and light.

The energy needed for the reaction to occur is less than the total energy released (Figure E-3).

Figure E-3 Representation of an exothermic reaction in which the heat content of the products is greater than the heat content of the reactants.

For an exothermic reaction, this gives a negative value for ΔH , since a larger value (the energy released in the reaction) is subtracted from a smaller value (the energy used for the reaction).

In a chemical reaction, reactants are converted into products by the breaking and making of chemical bonds. Bond breaking requires energy, while bond making releases energy. The balance between the two gives a positive or negative energy change for the reaction, and chemical reactions are classed as being either endothermic, with a positive energy change, or exothermic, with a negative energy change. Thus, an exothermic reaction is a chemical reaction that produces heat.

Combustion or burning of a fuel is a complex sequence of exothermic chemical reactions between a fuel (usually a hydrocarbon) and an oxidant accompanied by the production of heat or both heat and light.

See also: Endothermic Reaction.

Explosive Limits

The explosive limit of a gas or a vapor is the limiting concentration (in air) that is needed for the gas to ignite and explode. There are two explosive limits for any gas or vapor, the lower explosive limit (LEL) and the upper explosive limit (UEL). A fuel and oxygen (air) must exist in certain proportions, along with an ignition source, such as a spark or flame. The ratio of fuel and oxygen that is required varies with each combustible gas or vapor. The minimum concentration of a particular combustible gas or vapor necessary to support its combustion in air is the *lower explosive limit* (LEL) for that gas. Below this level, the mixture is too lean to burn. The maximum concentration of a gas or

vapor that will burn in air is the *upper explosive limit* (UEL). Above this level, the mixture is too rich to burn. The range between the LEL and the UEL is the flammable range for that gas or vapor.

Dusts also have upper and lower explosion limits, though the upper limits are hard to measure and of little practical importance. The LELs for many organic materials are in the range of 10 to 50 g/m³, which is much higher than the limits set for health reasons, as is the case for the LEL of many gases and vapors. Dust clouds of this concentration are hard to see through for more than a short distance, and normally only exist inside process equipment.

See also: Lower Explosive Limit, Lower Flammability Limit, Upper Explosive Limit, Upper Flammability Limit.

Extraction

Extraction is a process in which one or more components are separated selectively from a liquid or solid mixture, the feed (Phase 1), by means of a liquid immiscible solvent (Phase 2). The transfer of the components from the feed to the solvent is controlled by the solubility behavior of each component in the corresponding phase. Two phases result from the extraction step: one enriched (the extract phase) and the other depleted (the raffinate phase) in the components to be separated, respectively. In order to regenerate the solvent, another separation step (e.g., distillation) is finally required.

Liquid-liquid extraction is most widely used and will be considered within this laboratory. It is applied, e.g., to remove heavy metals or acids from wastewater or for the production of aromatic compounds from mixtures of hydrocarbons. Another application is gas-liquid extraction which is also called absorption.

Compared to distillation, extraction processes have the disadvantage that a new component is added to the system. This leads to additional impurities as complete immiscibility does only exist in theory. Furthermore, a subsequent separation process is required to regenerate the solvent. However, there are a number of situations in which extraction is advantageous, and they are: (i) one or more components in the mixture are not thermally stable, (ii) the components in the mixture have a high or low boiling point requiring vacuum or cryogenic distillation, which is very energy intensive, (iii) the boiling points of the components are very close or they form azeotropes, (iv) two components with very different boiling points have to be separated at the same time, and (v) the components to be separated (pollutants or valuable products) are only a small fraction of the mixture.

See also: Absorption, Biomass – Extraction, Distillation, Extractive Distillation.

Extractive Distillation

Extractive distillation is distillation in the presence of a miscible, high boiling, relatively non-volatile component, the solvent, which forms no azeotrope with the other components in the mixture. The method is used for mixtures having a low value of relative volatility, nearing unity. Such mixtures cannot be separated by simple distillation because the volatility of the two components in the mixture is nearly the same, causing them to evaporate at nearly the same temperature at a similar rate, making normal distillation impractical.

In extractive distillation, the solvent is specially chosen to interact differently with the components of the original mixture, thereby altering their relative volatility. Because these interactions occur predominantly in the liquid phase, the solvent is continuously added near the top of the extractive distillation column so that an appreciable amount is present in the liquid phase on all of the trays below. The mixture to be separated is added through second feed point further down the column. In the extractive column, the component having the greater volatility, not necessarily the component having the lowest boiling point, is taken overhead as a relatively pure distillate. The other component leaves with the solvent via the column bottoms. The solvent is separated from the remaining components in a second distillation column and then recycled back to the first column.

It is important to select a suitable separation solvent for this type of distillation. The solvent must alter the relative volatility by a wide enough margin for a successful result. The quantity, cost, and availability of the solvent should be considered. The solvent should be easily separable from the bottom product, and should not react chemically with the components or the mixture, or cause corrosion in the equipment. A classic example to be cited here is the separation of an azeotropic mixture of benzene and cyclohexane, where aniline is one suitable solvent.

Extractive distillation is used to recover aromatic hydrocarbon derivatives from, say, reformat fractions in the following manner. By means of preliminary distillation in a 65-tray pre-fractionator, a fraction containing a single aromatic can be separated from reformat, and this aromatic concentrate is then pumped to an extraction distillation tower near the top and aromatic concentrate enters near the bottom. A reboiler in the extractive distillation tower induces the aromatic concentrate to ascend the tower, where it contacts the descending solvent.

The solvent removes the aromatic constituents and accumulates at the bosom of the tower; the non-aromatic portion of the concentrate leaves the top of the tower and may contain approximately 1% of the aromatics. The solvent and dissolved aromatics are conveyed from the bottom of the extractive distillation tower to a solvent stripper, where fractional distillation separates the aromatics from the solvent as an overhead product. The solvent is recirculated to the extractive distillation tower, whereas the aromatic stream is treated with sulfuric acid and clay to yield a finished product of high purity.

See also: Distillation.

Explosive Limits

The explosive limit of a gas or a vapor is the limiting concentration (in air) that is needed for the gas to ignite and explode. Before a fire or explosion can occur, three conditions must be met simultaneously. A fuel (i.e., combustible gas) and oxygen (air) must exist in certain proportions, along with an ignition source, such as a spark or flame. The ratio of fuel and oxygen that is required varies with each combustible gas or vapor. The minimum concentration of a particular combustible gas or vapor necessary to support its combustion in air is defined as the lower explosive limit (LEL) for that gas. Below this level, the mixture is too lean (dilute) to burn. The maximum concentration of a gas or vapor that will burn in air is defined as the upper explosive limit (UEL). Above this level, the mixture is too rich to burn. The range between the lower explosive limit and the upper explosive limit is known as the flammable range for that gas or vapor. Concentrations of explosive gases are often given in terms of percent of lower explosive limit (%LEL).

Dusts also have upper and lower explosion limits, though the upper limits are hard to measure and of little practical importance. Lower explosive limits for many organic materials are in the range of 10 to 50 g/m³, which is much higher than the limits set for health reasons, as is the case for the lower explosive limit of many gases and vapors. Dust clouds of this concentration are hard to see through for more than a short distance, and normally only exist inside process equipment.

Extra Heavy Crude Oil

Extra heavy crude oil is a non-descript term (related to viscosity) of little scientific meaning that is usually applied to tar sand bitumen, which is generally capable of free flow under reservoir conditions. Thus, the general difference is that extra heavy crude oil, which may have properties similar to tar sand bitumen in the laboratory but, unlike tar sand bitumen in the deposit, has some degree of mobility in the reservoir or deposit.

Extra heavy crude oils can flow at reservoir temperature and can be produced economically, without additional viscosity-reduction techniques, through variants of conventional processes such as long horizontal wells, or multi-laterals. This is the case, for instance, in the Orinoco basin (Venezuela) or in offshore reservoirs of the coast of Brazil, but, once outside of the influence of the high reservoir temperature, these oils are too viscous at surface to be transported through conventional pipelines and require heated pipelines for transportation. Alternatively, the oil must be partially upgraded or fully upgraded or diluted with a low-boiling hydrocarbon fraction (such as aromatic naphtha) to create a mix that is suitable for transportation.

The largest accumulation of extra heavy crude oil is the Venezuelan Orinoco heavy-oil belt, which contains approximately 90% v/v of the world heavy crude oil reserves, when measured on an oil-in-place basis. In addition to extra-heavy Orinoco oil, South America also has technically recoverable heavy crude oil, so that, in total, approximately 61% v/v of the known technically recoverable heavy crude oil is in South America. However, the actual production data for heavy crude oil recovery is difficult to assess because of the loose and often arbitrary definitions that are employed.

Extraneous Mineral Matter

Extraneous mineral matter is the mineral matter that was brought into the coal-forming deposit by mechanical means from outside as, for example, dust by air or as mineral matter that was suspended or dissolved and carried by water.

The presence of the mineral matter in coal is even more apparent when the coal is examined in place in the bed, after being mined or finally prepared for market, and, finally, when the residue from its combustion is examined.

Extraneous mineral matter is apparent as definite horizontal layers of varying thickness and extent, as surface deposits or fillings in the vertical cleats, and more unusually as intrusions of clay-like (or other) material which occurs irregularly throughout the coal deposit. The horizontal layers that attain a considerable thickness may serve as a means of separating different coals or simply as separating the different phases of formation of one particular coal. Bands of this type are always regarded as being formed during the deposition of the coal precursors.

The mineral deposits in the shrinkage cracks or cleats, which may, for example, be kaolinite, calcite, gypsum, or pyrite, are usually thick surface deposits and may not always be present and were presumably deposited later in the coal-forming process. The larger adventitious bodies of foreign matter in the coal (such as clay veins, sandstone intrusions, and washouts) may be the result of rather unusual geological conditions during and after the time the coal beds were laid down. A large part of the mineral matter in marketed coal arises from the inclusion during mining of roof (or floor) rock of the impure streaks or of some of the large impurities. Such inclusions may be deliberate insofar as little effort is made to remove them during the mining operation, or they may be accidental in that their elimination during mining was not complete. The increasing use of mechanical methods of mining (particularly in large-scale strip operation) has supported the practice to do little exclusion during mining and to subject the coal to a cleaning process afterward.

ExxonMobil AGC-21 Process

Conversion of natural gas to liquids (GTL) utilizing Fischer-Tropsch (FT) hydrocarbon synthesis technology is an attractive option to bring additional liquids to market. The ExxonMobil advanced gas conversion process for the 21st Century (AGC-21)¹ is state-of-the-art gas-to-liquids technology that provides an option for utilization of gaseous products from biomass.

In the process, there are three key steps. In the first step, syngas is generated by contacting methane with steam and a limited amount of oxygen in a high capacity catalytic reactor. Hydrocarbon derivatives are synthesized in the second step at high alpha in a novel slurry reactor using new, high productivity catalysts operating at high levels of syngas conversion. The full-range, primarily normal paraffin product contains significant 650°F+ waxy material that is a solid at room temperature and melts above 122°C (250°F), unsuitable for pipelining or transporting in conventional crude carriers. The final step, accomplished with proprietary catalysts in a packed bed reactor, converts wax to high-quality liquids that make excellent feeds for refineries and chemical plants and directly marketable products in some instances, such as lube base stocks or specialty solvents.

The chemistry of each step is straightforward yet becomes more complex as processes go to high yield and selectivity. Oxygen, methane, and steam ratios are carefully controlled to produce syngas (carbon monoxide and hydrogen) at stoichiometric proportions of approximately 2.1 to 1 hydrogen to carbon monoxide.

Fabric Filter

A fabric filter is made from fabric materials and used for removing particulate matter from gas streams. Commonly known as baghouses, fabric collectors use filtration to separate dust particulates from dust-laden gas streams. They are one of the most efficient and cost-effective types of dust collectors available and can achieve a collection efficiency of more than 99% for fine particulate matter.

The filter unit consists of one or more isolated compartments containing rows of fabric bags in the form of round, flat, or shaped tubes, or pleated cartridges. Particle-laden gas passes up (usually) along the surface of the bags then radially through the fabric. Particles are retained on the upstream face of the bags, and the cleaned gas stream is vented to the atmosphere. The filter is operated cyclically, alternating between relatively long periods of filtering and short periods of cleaning. During cleaning, dust that has accumulated on the bags is removed from the fabric surface and deposited in a hopper for subsequent disposal.

As the dusty emissions flow through the filter media (typically cotton, polypropylene, Teflon, or fiberglass), particulate matter is collected on the bag surface as a dust cake. Fabric filters are generally classified based on the filter bag cleaning mechanism employed and operate with collection efficiencies above 99%. The layer of dust, or dust cake, collected on the fabric is primarily responsible for such high efficiency. The cake is a barrier with tortuous pores that trap particles as they travel through the cake. Gas temperatures up to approximately 260°C (500°F), with surges to approximately 285°C (550°F) can be accommodated routinely in some configurations. Most of the energy used to operate the system appears as pressure drop across the bags and associated hardware and ducting.

Fabric filters are used where high-efficiency particle collection is required. Limitations are imposed by gas characteristics (temperature and corrosivity) and particle characteristics (primarily stickiness) that affect the fabric or its operation and that cannot be economically accommodated.

Process variables include particle characteristics, gas characteristics, and fabric properties. The most important design parameter is the air- or gas-to-cloth ratio (the amount of gas in ft³/min that penetrates one ft² of fabric), and the usual operating parameter of interest is pressure drop across the filter system. The major operating feature of fabric filters that distinguishes them from other gas filters is the ability to renew the filtering surface periodically by cleaning.

Fabric filters can be categorized by several means, including type of cleaning (shaker, reverse air, pulse-jet), direction of gas flow (from inside the bag towards the outside or vice versa), location of the system fan (suction or pressure), or size (low, medium, or high gas flow quantity). Of these four approaches, the cleaning method is probably the most distinguishing feature.

Fast-Neutron Reactor

A fast-neutron reactor (FNR, or fast reactor) is a type of nuclear reactor in which the fission chain reactor is sustained by Fast-Neutrons as opposed to thermal neutrons that are the active principle of thermal-neutron reactors. The Fast-Neutron reactor does not need a neutron moderator but does require nuclear fuel that is relatively rich in fissile (fissionable) material when compared to the fuel required for a thermal-neutron reactor.

See also: Nuclear Reactor – Fast-Neutron Reactor.

Fast Pyrolysis

Fast pyrolysis (rapid pyrolysis) is a thermal process in which biomass is rapidly heated to a carefully controlled temperature (approximately 400 to 600°C, 750 to 1,110°F), then very quickly cool the volatile products formed in the reactor. The process offers the unique advantage of producing a liquid that can be stored and transported and has been developed in many configurations. The fast heating rates used in fast pyrolysis allow the conversion of thermally unstable compounds before they produce undesired coke.

Fast pyrolysis units are designed to produce bio-oil by heating biomass to the designated temperature less than one second in the absence of oxygen. The process is not feedstock-specific. Most types of biomass feedstock can be used in the fast pyrolysis process to make bio-oil. There is no change in the process, and the yield and properties of the product are determined by the properties of the feedstock.

One option for the process is to build the pyrolysis unit near to the source and move the bio-oil to a biorefinery. Another benefit is that you can use this technology which is flexible insofar as it does not need chemicals or enzymes that have to be specific to a certain type of biomass feedstock.

Fast pyrolysis is one of the most promising methods for biofuel production. The reaction conditions allow the conversion of thermally unstable biomass compounds to a liquid product (bio-oil) while minimizing undesired reactions (i.e., coke and gas formation). The bio-oils are acidic combustible liquids containing more than 300 compounds that degrade with time.

Addition of heterogeneous catalysis to fast pyrolysis (catalytic fast pyrolysis) has the potential to significantly change the products produced and the product distribution.

Fat Oil

Fat oil is the bottom oil or enriched oil drawn from the absorber (as opposed to lean oil) in a gas cleaning process.

See also: Absorption, Gas Cleaning, Gas Processing, Gas Treating.

Fats And Greases

The proper categorization of fats and greases may be debatable since those are by-products of the reduction of animal biomass into component parts. However, most fats and greases, and some oils, are not available for bioenergy use until after they become a post-consumer waste stream; it seems appropriate for them to be included in the tertiary biomass category. Vegetable oils derived from processing of plant components and used directly for bioenergy (e.g., soybean oil used in biodiesel) would be a secondary biomass resource, though amounts being used for bioenergy are most likely to be tracked together with fats, greases, and waste oils.

The categorization of fats and greases within biomass may be debatable since those are by-products of the reduction of animal biomass into component parts. However, animal fats are a type of biomass, and since most fats and greases, and some oils, are not available for bioenergy use until after they become a post-consumer waste stream, it is appropriate for fats and greases to be included in the tertiary biomass category.

Fatty Acids

Until the refining of crude oil was developed during the 19th century, vegetable oils, especially the non-edible varieties (Table F-1), formed an important source of heat and light.

Table F-1 Examples of saturated and unsaturated fatty acids.

Acid*	Carbon atoms	Double bonds
Arachidic	20	0
Behemic	22	0
Caprylic acid	8	0
Capric acid	10	0
Cerotic	26	0
Eicosenoic	20	1
Elaidic	18	1
Erucic	22	1
Lauric	12	0
Lignoceric	24	0
Linoleic	18	2
Myristic	14	0
Oleic	18	1
Palmitic	16	0
Sapienic	16	1
Stearic	18	0

*Listed alphabetically.

Usually, the seeds, which store much higher concentration of fatty oil than any other part of the plant, are used for extracting the oil. Most of the common oil seeds contain 20-30% w/w of the oil and in some cases in excess of 50% w/w (Table F-2).

Table F-2 Percentage of fatty acid types for different oils.

Oil	C16:0	C16:1	C18:0	C18:1	C18:2	C18:3*
Corn	6.0	-	2.0	44.0	48.0	-
Cottonseed	28.3	-	0.9	13.3	57.5	-
Olive	14.6	-	-	75.4	10.0	-
Palm	42.6	0.3	4.4	40.5	10.1	0.2
Peanut	11.4	-	2.4	48.3	32.0	0.9
Rapeseed	3.5	0.1	0.9	54.1	22.3	-
Safflower	7.3	0.1	1.9	13.5	77.0	-
Soybean	11.9	0.3	4.1	23.2	54.2	6.3
Sunflower	6.4	0.1	2.9	17.7	72.9	-
Tallow	29.0	-	24.5	44.5	-	-
WCO**	20.4	4.6	4.8	52.9	13.5	0.8

*The first number is the total number of carbon atoms in the acid molecule, and the second number is the carbon atom on which the double bond is located.

**WCO: waste cooking oil.

The techniques for the extraction of oil from the seeds are relatively simple and may involve one or more of the following processes, viz., (i) pressing, (ii) cooking in water, and (iii) solvent extraction. Some of the non-edible oils that are being tried as transport fuel for vehicles are the oils of Pongamia, mahua, neem, and Jatropha.

By way of definition, in chemistry, particularly in biochemistry, a **fatty acid** is a carboxylic acid with a long carbon (aliphatic) chain, which is either saturated or unsaturated. Most naturally occurring fatty acids have an unbranched carbon chain of an even number of carbon atoms, from 4 to 28 carbon atoms (Table F-3).

Table F-3 Examples of the structural characteristics of selected fatty acids.

Unsaturated fatty acids have one or more carbon-carbon ($\text{C}=\text{C}$) double bonds which can confer either *cis* or *trans* isomers.

A *cis* configuration means that the two hydrogen atoms adjacent to the double bond stick out on the same side of the chain. The rigidity of the double bond freezes its conformation and, in the case of the *cis* isomer, causes the chain to bend and restricts the conformational freedom of the fatty acid. The more double bonds the chain has in the *cis* configuration, the less flexibility it has. When a chain has many *cis* bonds, it becomes quite curved in its most accessible conformations. For example, oleic acid, with one double bond, has a slight bend in the molecule whereas linoleic acid, with two double bonds, has a more pronounced bend and alpha-linoleic acid, with three double bonds, favors a hooked shape to the molecule. The effect of this is that, in restricted environments, such as when fatty acids are part of a phospholipid in a lipid bilayer, or triglycerides in lipid droplets, *cis* bonds limit the ability of fatty acids to be tightly packed, and therefore can affect the melting temperature of the membrane or of the fat. *Cis* unsaturated fatty acids, however, increase cellular membrane fluidity, whereas *trans* unsaturated fatty acids do not.

By contrast, a *trans* configuration, by contrast, means that the adjacent two hydrogen atoms lie on *opposite* sides of the chain. As a result, they do not cause the chain to bend much, and their shape is similar to straight saturated fatty acids. In most naturally occurring unsaturated fatty acids, each double bond has three (*n*-3), six (*n*-6), or nine (*n*-9) carbon atoms after it, and all double bonds have a *cis* configuration. Most fatty acids in the *trans* configuration (*trans* fats) are not found in nature and are the result of human processing (such as hydrogenation). The geometric differences between the various types of unsaturated fatty acids, as well as between saturated and unsaturated fatty acids, play an important role in biological processes, and in the construction of biological structures (such as cell membranes).

Vegetable oils are the esters of glycerol and fatty acids. In this form, they are not quite suitable as substitutes for petrol or diesel, though a mixture of certain percentage (up to 30%) of oil with diesel is found to work reasonably well. However, they can be modified to get more suitable fuels that can fully substitute diesel or petrol. One way is by cracking them at higher temperatures on certain metal oxide catalysts, which yields hydrocarbon derivatives having fuel qualities similar to those of petrol/diesel. The other method is a chemical reaction called transesterification. In this process, the glyceryl esters of the fatty acids in the oil are converted into their methyl esters by an acid-catalyzed reaction of oils with methanol. The methyl esters are better suited to be used as vehicle fuel, either in pure form or by blending with diesel.

Feedstock

The feedstock is the raw material for a process that is used to create new products as defined by the process equipment and parameter. The term raw material can encompass the entirety of what goes into making a product. The feedstock is typically a single, uniform, raw material that is given as an input into a process, usually in large quantities. In some cases, the feedstock to a process may be a product for a secondary that has previously been reduced from the original raw feedstock.

Many process units operate continuously (as opposed to batch operation) at steady state or approximately steady state for long periods of time (months to years). The high capacity also makes process optimization and advanced process control desirable.

See also: Refining.

Fermentation

A number of processes allow biomass to be transformed into gaseous fuels such as methane or hydrogen. One pathway uses algae and bacteria that have been genetically modified to produce hydrogen directly instead of the conventional biological energy carriers. A second pathway uses plant material such as agricultural residues in a fermentation process leading to biogas from which the desired fuels can be isolated. This technology is established and in widespread use for waste treatment, but often with the energy produced only for onsite use, which often implies less than maximum energy yields. Finally, high-temperature gasification supplies a crude gas, which may be transformed into hydrogen by a second reaction step. In addition to biogas, there is also the possibility of using the solid by-product as a biofuel.

Fermentation feedstocks require pretreatment by chemical, physical, or biological means to open up the structure of biomass and reduce the complex carbohydrates to simple sugars. This type of pretreatment is often referred to as hydrolysis. The resulting sugars can then be fermented by the yeast and bacteria employed in the process. Feedstocks high in starch and sugar are most easily hydrolyzed. Cellulosic feedstocks, including the major fraction of organics in MSW, are more difficult to hydrolyze, requiring more extensive pretreatment. Fermentation is generally used industrially to convert substrates such as glucose to ethanol for use in beverage, fuel, and chemical applications and to other chemicals (e.g., lactic acid used in producing renewable plastics) and products (e.g., enzymes for detergents). Strictly speaking, fermentation is an enzymatically controlled anaerobic process although the term is sometimes more loosely applied to include aerobic processing as well.

Traditional fermentation plants producing biogas are in routine use, ranging from farms to large municipal plants. As feedstock, they use manure, agricultural residues, urban sewage, and waste from households, and the output gas is typically 64% methane. The biomass conversion process is accomplished by a large number of different agents, from the microbes decomposing and hydrolyzing plant material, over the acidophilic bacteria dissolving the biomass in aquatic solution, and to the strictly anaerobic methane bacteria responsible for the gas formation. Operating a biogas plant for a period of some months usually makes the bacterial composition stabilize in a way suitable for obtaining high conversion efficiency (typically above 60%, the theoretical limit being near 100%), and it is found important not to vary the feedstock compositions abruptly if optimal operation is to be maintained. Operating temperatures for the bacterial processes are only slightly above ambient temperatures, e.g., in the mesophilic region around 30°C.

The production of ethanol from corn is a mature technology that holds much potential. Substantial cost reductions may be possible, however, if cellulose-based feedstocks are used instead of corn. The feed for all ethanol fermentations is sugar – traditionally a hexose (a six-carbon or “C6” sugar) such as those present naturally in sugar cane, sugar beet, and molasses. Sugar for fermentation can also be recovered from starch, which is actually a polymer of hexose sugars (*polysaccharide*).

Biomass, in the form of wood and agricultural residues such as wheat straw, is viewed as a low-cost alternative feed to sugar and starch. It is also potentially available in far greater quantities than sugar and starch feeds. As such, it receives significant attention as a feed material for ethanol production. Like starch, wood and agricultural residues contain polysaccharides. However, unlike starch, while the cellulose fraction of biomass is principally a polymer

of easily fermented C6 sugars, the hemicellulose fraction is principally a polymer of C5 sugars; with quite different characteristics for recovery and fermentation, the cellulose and hemicellulose in biomass are bound together in a complex framework of crystalline organic material known as lignin.

There are several different methods of hydrolysis: (i) concentrated sulfuric acid, (ii) dilute sulfuric acid, (iii) nitric acid, and acid pretreatment followed by enzymatic hydrolysis. The greatest potential for ethanol production from biomass, however, lies in enzymatic hydrolysis of cellulose. The enzyme cellulase, now used in the textile industry to stone wash denim and in detergents, simply replaces the sulfuric acid in the hydrolysis step. The cellulase can be used at lower temperatures, 30 to 50°C, which reduces the degradation of the sugar. In addition, process improvements now allow simultaneous saccharification and fermentation (SSF). In the saccharification and fermentation process, cellulase and fermenting yeast are combined, so that as sugars are produced, the fermentative organisms convert them to ethanol in the same step.

Once the hydrolysis of the cellulose is achieved, the resulting sugars must be fermented to produce ethanol. In addition to glucose, hydrolysis produces other six-carbon sugars from cellulose and five-carbon sugars from hemicellulose that are not readily fermented to ethanol by naturally occurring organisms. They can be converted to ethanol by genetically engineered yeasts that are currently available, but the ethanol yields are not sufficient to make the process economically attractive. It also remains to be seen whether the yeasts can be made hardy enough for production of ethanol on a commercial scale.

The fermentation processes to produce propanol and butanol from cellulose can be difficult to execute, and the *Clostridium acetobutylicum* that is currently used to perform these conversions produces an extremely unpleasant smell, and this must be taken into consideration when designing and locating a fermentation plant. This organism also dies when the butanol content of whatever it is fermenting rises to 7%. For comparison, yeast dies when the ethanol content of its feedstock reaches 14%. Specialized strains can tolerate even greater ethanol concentrations – the so-called turbo yeast can withstand up to 16% ethanol. However, if ordinary *Saccharomyces* yeast can be modified to improve its ethanol resistance, scientists may yet one day produce a strain of the Weizmann organism with a butanol resistance higher than the natural boundary of 7%. This would be useful because butanol has a higher energy density than ethanol, and because waste fiber left over from sugar crops used to make ethanol could be made into butanol, raising the alcohol yield of fuel crops without there being a need for more crops to be planted.

Wet milling and dry milling are the means by which grain and straw fractions are processed into a variety of end products. The processes encompass fermentation and distilling of grains (wheat, rye, or maize). Wet milling starts with water-soaking the grain adding sulphur dioxide to soften the kernels and loosen the hulls, after which it is ground. It uses well-known technologies and allows separation of starch, cellulose, oil, and proteins. Dry milling grinds whole grains (including germ and bran). After grinding, the flour is mixed with water to be treated with liquefying enzymes and, further, cooking the mash to break down the starch. This hydrolysis step can be eliminated by simultaneously adding saccharifying enzymes and fermenting yeast to the fermenter (simultaneous saccharification and fermentation).

After fermentation, the mash (called *beer*) is sent through a multi-column distillation system, followed by concentration, purification, and dehydration of the alcohol. The residue mash (stillage) is separated into a solid (wet grains) and liquid (symp) phase that can be combined and dried to produce distiller's dried grains with soluble constituents, to be used as cattle feed. Its nutritional characteristics and high vegetable fiber content make distiller's dried grains with soluble constituents unsuitable for other animal species.

In separate hydrolysis and fermentation processes, the hydrolysis is carried out in one vessel and the hydrolysate is then fermented in a second reactor. Approximately 73% of the cellulose is converted to ethanol in 48 hr, while the remainder of the cellulose, hemicelluloses, and lignin is burned. The most important parameters are the hydrolysis section yield, product quality, and the required enzyme loading which are all interrelated. Yields are typically higher in more dilute systems where inhibition of enzymes by glucose and cellobiose is minimized. Increasing the amount of enzyme loading can help to overcome inhibition and increase yield and concentration. Increased reaction times also make higher yields and concentrations. Cellulase enzymes from different organisms can result in markedly different performances.

In simultaneous saccharification and fermentation, both the hydrolysis and fermentation are carried out in the same vessel. In this process, yeast ferments the glucose to ethanol as soon as the glucose is produced, preventing

the sugars from accumulating and the end product inhibition. Using the yeast, *Candida brassicae* and the Genencor enzyme (by Genencor International), the yield is increased to 79% and the ethanol concentration produced is 3.7%.

Even in simultaneous saccharification and fermentation, the cellobiose (the soluble sugar) inhibition occurs to an appreciable extent. The hydrolysis is carried out at 37°C (99°F), and increasing the temperature increases the reaction rate; however, the ceiling temperature is limited by the yeast cell viability. The concentration of ethanol is also a limiting factor (This was tested by connecting a flash unit to the SSF reactor and removing the ethanol periodically. This technique showed higher productivities up to 44%). Recycling the residual solids may also increase the process yield. However, the most important limitation in the enzyme recycling comes from the presence of lignin, which is inert to the enzyme. High recycling rates increase the fraction of lignin in the reactor and cause handling difficulties.

In spite of the considerable efforts given to the fermentative alcohols, industrial applications have been delayed because of the high cost of production which depends primarily on the energy input to the purification of dilute end products and on the low productivities of cultures. These two points are linked to inhibition phenomena.

Along with the conventional unit operations, liquid-liquid extraction with biocompatible organic solvents, distillation under vacuum, and selective adsorption on the solids have demonstrated the technical feasibility of the extractive fermentation concept.

Membrane separation processes, which decrease biocompatibility constraints, have been proposed. In fact, the concept of supported liquid membranes has been reported and proposed. This method minimizes the amount of organic solvents involved and permits simultaneous realization of the extraction and recovery phases. Enhanced volumetric productivity and high substrate conversion yields are possible.

Fermentation Chemistry

The principal components of most plant materials are commonly described as lignocellulosic biomass. This type of biomass is mainly composed of the compounds called cellulose, hemicellulose, and lignin. Cellulose is a primary component of most plant cell walls and is made up of long chains of the 6-carbon sugar, glucose, that are arranged in bundles (often described as crystalline bundles). The cellulose molecules in the plant cell wall are interconnected by another molecule called hemicellulose.

The hemicellulose is primarily composed of the 5-carbon sugar, xylose. Besides cellulose and hemicellulose, another molecule called lignin is also present in significant amounts and provides the structural strength for the plant. Technological developments have recently introduced a variety of processes of extracting and dissolving the cellulose and hemicellulose to produce sugars in such a form that can be readily fermented to ethanol. Generally speaking, appropriate pre-treatment can liberate the cellulose and hemicellulose from the plant material. Further treatment using chemicals, enzymes, or microorganisms can also be applied to liberate simple sugars from the cellulose and hemicellulose, thus making them available to microorganisms for fermentation to ethanol.

The first step in the conversion of sugars to ethanol involves cellulose hydrolysis that is essentially cleaving the chemical bonds in the cellulose to produce glucose.

The hydrolysis of cellulose is critical for biofuel production because only glucose, not cellulose, can be consumed by the bacteria used in fermentation to produce biofuel. Cellulose derivatives have crystalline structures due to the dense packing of cellulose chains. They are very stable under many chemical conditions and are not soluble in water, many organic solvents, weak acids, or bases. The crystalline structure can be destroyed and turned into amorphous form under high temperature (>300°C, 570°F) and pressure. There are normally two ways to hydrolyze cellulose: chemically and enzymatically. The chemical method is to use concentrated strong acids to hydrolyze cellulose under high temperature and pressure. However, this method is not preferred by biofuel industry, because toxic by-products remaining in the glucose products will be introduced into the fermentation step, affecting the fermenting bacteria/yeast. Hence, the milder enzymatic method seems to be a much more potential candidate to hydrolyze cellulose.

The enzymatic method uses bacteria-secreted proteins to hydrolyze cellulose which method involves enzymes, such as cellulase. These enzymes play different roles cooperatively in the hydrolysis of cellulose: some cleave the

cellulose chain from the middle into fragments containing 4 to 5 glucose units, some break down these fragments into smaller units of two glucoses, and some finally turn these small units into single glucose unit.

Once the large molecules are extracted from plant cells, they can be broken down into their component sugars using enzymes or acids. The sugars can be subsequently converted to ethanol using appropriately selected microorganisms via fermentation.

The fermentation of ethanol from 6-carbon sugars follows the following stoichiometric equation by which one mole of glucose produces 2 moles of ethanol and 2 moles of carbon dioxide. Thus:

Hemicellulose is made up of the 5-carbon sugar, xylose, arranged in chains with other minor 5-carbon sugars interspersed as side chains. In a similar manner to cellulose, the hemicellulose can also be extracted from the plant material and treated to liberate xylose that, in turn, can be fermented to produce ethanol. However, xylose fermentation is not as straightforward as glucose fermentation. Depending on the microorganism and conditions employed, a number of different fermentation paths are possible and the products can include ethanol, carbon dioxide, and water.

Fermentation Plants

Traditional fermentation plants producing biogas are in routine use, ranging from farm-size plants to large municipal plants. As feedstock, they use manure, agricultural residues, urban sewage, and waste from households, and the output gas is typically 64% methane.

The biomass conversion process is accomplished by a large number of different agents, from the microbes decomposing and hydrolyzing plant material, over the acidophilic bacteria dissolving the biomass in aquatic solution, and to the strictly anaerobic methane bacteria responsible for the gas formation. Operating a biogas plant for a period of some months usually makes the bacterial composition stabilize in a way suitable for obtaining high conversion efficiency (typically above 60%, the theoretical limit being near 100%), and it is found important not to vary the feedstock compositions abruptly if optimal operation is to be maintained. Operating temperatures for the bacterial processes are only slightly above ambient temperatures, e.g., in the mesophilic region around 30°C (86°F).

See also: Fermentation, Fermentation Chemistry.

Ferrel Cell

The Ferrel cell is operative from 30° latitude to 60° latitude and produces prevailing westerly winds at the surface within these latitudes because some of the air sinking at 30° latitude continues traveling northward toward the poles and the Coriolis force bends it to the right (in the Northern Hemisphere). This air is still warm and at roughly 60° latitude approaches cold air moving down from the poles. With the converging air masses at the surface, the low surface pressure at 60° latitude causes air to rise and form clouds. Some of the rising warm air returns to 30° latitude to complete the Ferrel cell.

The two air masses at 60° latitude do not mix well and form the polar front which separates the warm air from the cold air. Thus, the polar front is the boundary between warm tropical air masses and the colder polar air moving from the north. The polar jet stream aloft is located above the polar front and flows generally from west to east. The polar jet is strongest in the winter because of the greater temperature contrasts than during the summer. Waves along this front can pull the boundary north or south, resulting in local warm and cold fronts which affect the weather at particular locations.

Above 60° latitude, the polar cell circulates cold, polar air equatorward. The air from the poles rises at 60° latitude where the polar cell and Ferrel cell meet, and some of this air returns to the poles completing the polar cell. Because the wind flows from high to low pressure and taking into account the effects of the Coriolis force, the winds above 60° latitude are prevailing easterlies.

In summary, the Ferrel cell is a thermally indirect cell because it is driven by the motions of the cells on either side. At upper levels, the model predicts easterly motion while at the surface, there is a strong belt of surface midlatitude westerlies. However, in reality, upper level westerlies in midlatitudes are observed because at upper levels, there is high pressure in the equator (due to higher temperature) and lower temperature at the poles. Thus, there is a pressure gradient from equator to pole and the actual wind is deflected due to Coriolis, so this causes predominant westerlies at upper levels that are stronger in the winter and, thus, the weather systems migrate from west to east.

Ferrox Process

Removal of large amounts of hydrogen sulfide from gas streams is accomplished by the Ferrox process. The process is based on the same chemistry as the iron oxide process except that it is fluid and continuous. The Ferrox process is also used to manage combustion residues in an environmentally safe way at a low cost. Compared to the costs of a traditional cement stabilization, the Ferrox[®]-process has advantages in reducing the overall mass of the residue that has to be disposed combined with a good stabilization.

The process stabilizes the residues, whereby the release of heavy metals and salts is substantially reduced compared to the untreated residues. The process does not yield a new heavy metal-polluted waste stream, but immobilizes the heavy metals in the residue. The salts are extracted from the residues during the process, and the result is a stabilized residue, which is easy to dispose of in an environmentally safe way.

Fibers

Fibers are a class of materials that are continuous filaments or are in discrete elongated pieces, similar to lengths of thread. Natural fibers include those produced by plants, animals, and geological processes and are biodegradable over time. They can be classified according to their origin: (i) vegetable fibers, (ii) wood fibers, (iii) animal fibers, and (iv) mineral fibers.

Vegetable fibers are generally based on arrangements of cellulose, often with lignin: examples include cotton, hemp, jute, and flax. Plant fibers are employed in the manufacture of paper and textile (cloth), and dietary fiber is an important component of human nutrition.

Wood fiber is from tree sources. Forms include groundwood, thermo-mechanical pulp (TMP), and bleached or unbleached kraft or sulfite pulps. Kraft and sulfite, also called sulfite, refer to the type of pulping process used to remove the lignin bonding the original wood structure, thus freeing the fibers for use in paper and engineered wood products such as fiberboard.

Animal fibers consist largely of particular proteins. Examples are spider silk, sinew, catgut, wool, hair such as cashmere, mohair, and angora, and fur such as sheepskin, rabbit, mink, fox, and beaver.

Mineral fibers comprise asbestos, which is the only naturally occurring long mineral fiber. Short, fiber-like minerals include wollastonite, attapulgite, and halloysite.

Fibers are classified by their chemical origin, falling into two groups or families: natural fibers and manufactured fibers. Manufactured fibers are also referred to as man-made or synthetic fibers.

Natural Fibers

Natural fibers are produced by plants and animals, or have a mineral origin: No chemical modification or man-made polymerization process is used to create them, which differentiates them from man-made or synthetic fibers. There are many processing possibilities, e.g., they can be spun into filaments, threads, or ropes, and then they can be woven, knitted, matted, or bound. Plant fibers are mainly composed of cellulose, hemicellulose, and lignin, but also to a minor extent, fats, waxes, pectin, water-soluble substances, and color-carrying substances are included. The shares of these substances vary from fiber to fiber. Also, the indicated properties of natural fibers can have considerable

variations (depending on the growing conditions and the harvesting time, extraction methods, treatment, as well as storage procedures) and will, therefore, serve only as a rough guideline.

Utilization of natural fibers has a long tradition in cultures around the world (e.g., for the production of clothing, building materials, and fishing nets); therefore, people who deal with traditional fiber types do not necessarily tend to refer to the relatively new term “biorefinery.” However, the possibilities of sustainably using several plant parts (seeds, lignocellulose parts of lower value) for various purposes, replacing less sustainable products (such as fossil-resource-based materials) and increasing regional added-value bring natural fibers into the limelight again in the context of the discussion of building a biobased economy. Regarding technical applications, the largest share of natural fibers is still used for traditional applications such as yarns, twines, and clothes; other applications are pulp and paper (especially specialty papers), composites (e.g., for the automotive industry), geo- and agro textiles, insulation products, and by-product utilization (e.g., animal bedding, construction material, gardening and boards), and for the purpose of energy.

Man-made Fibers

Man-made fibers are either significantly modified natural fibers (so-called regenerates, mostly cellulose), mineral (inorganic) man-made fibers, or synthetic fibers (man-made monomers are polymerized and processed into fibers). Man-made fibers, such as nylon, polyester, and rayon, are produced by chemical reactions controlled by people, rather than occurring naturally. The term synthetic fibers is often used to designate man-made fibers; however, to many people, this term has a negative connotation, meaning inauthentic, artificial, or fake.

Man-made cellulose fibers, in contrast to natural fibers, are not defined by a single feedstock (e.g., viscose can be produced from wood as well as from cotton linter). The characterization of these fibers depends on the production processes used and the final fiber properties. Important man-made cellulose-based fibers include Viscose, Modal, Lyocell, and acetate fibers, which can be produced as staple or as filament fibers. The main source of man-made cellulosic fibers is wood. A variety of processes is available to separate the cellulosic wood fibers, which are often followed by different bleaching procedures.

Fiber products are products derived from fibers of herbaceous and woody plant materials; examples include pulp, composition board products, and wood chips for export.

Filters

Filters can be used to remove particles from liquid streams and from gas streams. Pressure filters are generally automatic devices in which the contaminated water is sucked inwards through a series of leaves on which a filter cake forms.

The filtration process involves a filter medium, over which water flows. This filter media blocks passage of contaminants through physical obstruction, chemical adsorption, or a combination of both processes. Material construction of the filter media varies widely, but the most effective media are made from carbon or a combination of carbon with other elements. Generally, water goes through several stages of filtration to ensure that each filter media will remove the ultimate number of contaminants. Water normally passes through a water filter at a relatively low speed, in order to ensure adequate contact time with the filter media. Once the water has passed through the required stages of filtration, it emerges as pure drinking water, free from contamination.

The filter may be used to remove particles from shale oil retort waters as the first stage in a treatment system, or it can be used to dewater the sludge products from other separators. The filter cake is generally low in moisture, which eases disposal problems. Vacuum filtration can also be used to remove suspended particles from wastewater but is more suitable for dewatering concentrated streams and sludge. In the rotary vacuum filter, a rotating drum dips into a trough filled with wastewater, and suction is applied to the inside of the drum. Water is drawn through the perforated surface of the drum, and solids are deposited on the outside as a filter cake. As the drum rotates, the dewatered sludge is scraped off and falls into a receiving trough. A filter press is functionally similar except that the wastewater is sucked or pumped through a series of plate-and-frame assemblies. The dewatered sludge is periodically removed from the filter medium by mechanical cleaning.

Ultrafiltration, in which the wastewater is forced through a membrane, is often used for separation of oil and water. It is generally limited to separation of chemically stabilized emulsions and is not suitable for mechanical emulsions. In multimedia filters, granular materials such as sand form a filtering bed through which the wastewater is pumped. The water passes through a series of layers with granules of increasingly fine size. The collected solids are subsequently removed by back-flushing with clean water. This filter produces sludge, rather than a dry cake, which requires additional dewatering before disposal. The multimedia filter is generally more economical than pressure filters for high flow rates and dilute slurries.

See also: Fabric Filter, Gas Cleaning, Gas Processing, Gas Treating.

Filter Tubes

At some stage of gas processing, the gas flow is directed to a unit that contains a series of filter tubes. As the velocity of the stream reduces in the unit, primary separation of remaining contaminants occurs due to gravity. Separation of smaller particles occurs as gas flows through the tubes, where they combine into larger particles which flow to the lower section of the unit. Further, as the gas stream continues through the series of tubes, a centrifugal force is generated which further removes any remaining water and small solid particulate matter.

See also: Fabric Filter, Filters, Filtration, Gas Cleaning, Gas Processing, Gas Treating.

Filtration

Filtration is a mechanical or physical operation which is used for the separation of solids or small particles from fluids (liquids or gases) by interposing a medium to fluid flow through which the fluid can pass, but the solids (or at least part of the solids) in the fluid are retained. It has to be emphasized that the separation is NOT complete, and it will depend on the pore size and the thickness of the medium as well as the mechanisms that occur during filtration.

The filtration process separates particles and fluid from a suspension, and the fluid can be either a liquid or a gas (or a supercritical fluid). To separate a mixture of chemical compounds, a solvent is chosen which dissolves one component, while not dissolving the other. By dissolving the mixture in the chosen solvent, one component will go into the solution and pass through the filter, while the other will be retained. Filtration also cleans up air streams or other gas streams. Furnaces use filtration to prevent the furnace elements from fouling with particulates. Pneumatic conveying systems often employ filtration to stop or slow the flow of material that is transported, through the use of a baghouse.

Filtration processes can be subdivided into three broad categories: (i) cake filtration, (ii) depth filtration, and (iii) surface filtration. In cake filtration, the porous barrier holds back the solid particles, which build up into a steadily thickening cake as the filtration progresses. However, the cake must be sufficient to allow the fluid to flow through it as the cake builds up. In depth filtration, the porous barrier is a relatively thick layer of coarse material. This allows clear fluid to pass through while trapping the solid particles in the relatively coarse spaces between the particles forming the filter bed. In surface filtration, the porous barrier is a membrane of controlled pore size. The solid particles are stopped if they are too large to pass through the pores in the barrier. Thus, the filtration in this case is essentially a straining process, much like screening. However, because the filtration barrier tends to blind (that is, plug) the pores with solid particles, the filtration rate decreases as the filtration progresses and the filter is completely plugged before a cake can be formed.

There are two main types of filter media: (i) a solid sieve which traps the solid particles, with or without the aid of filter paper, and (ii) a bed of granular material which retains the solid particles as it passes. The first type allows the solid particles, i.e., the residue, to be collected intact; the second type does not permit this. However, the second type is less prone to clogging due to the greater surface area where the particles can be trapped. Also, when the solid particles are fine, it is often more economic and easier to discard the contaminated granules than to clean the solid sieve.

Filtration is a more efficient method for the separation of mixtures than decantation, but is much more time consuming. If small amounts of solution are involved, most of the solution may be soaked up by the filter medium.

An alternative to filtration is centrifugation in which a mixture of solid and liquid particles is centrifuged to force the (usually) denser solid to the bottom, where it often forms a firm cake. The liquid above can then be decanted.

Fire Point and Flash Point

The *fire point* is the temperature to which the gas must be heated under the prescribed conditions of the test method to burn continuously when the mixture of vapor and air is ignited by a specified flame (ASTM D92).

Flash point is the temperature at which the ignition source will ignite the testing sample. The flash point is determined by heating the sample of fuel in a container and passing the flame over the surface of the sample. If the temperature is at or above the flash point, the vapor will ignite and an easily detectable flash can be observed. The flash produced need not be sustained for a long time. Whereas the fire point is the minimum temperature at which the vapor of the fuel steadily burns at least for five seconds once ignited. Flash point and fire point are the property that directly signifies whether the fuel is safely transportable; it is not related to engine performance.

From the viewpoint of safety, information related to the flash point is of most significance at or slightly above the maximum temperatures (30 to 60°C, 86 to 140°F) that may be encountered in storage, transportation, and use of liquid crude oil products, in either closed or open containers. In this temperature range, the relative fire and explosion hazard can be estimated from the flash point. For products with flash point below 40°C (104°F), special precautions are necessary for safe handling. Flash points above 60°C (140°F) gradually lose their safety significance until they become indirect measures of some other quality.

The fire point and the flash depend upon the volatility of the fuel – volatility is the tendency of the substance to vaporize, and it is related to the vapor pressure of the fuel at that particular temperature. The fuel exhibiting higher vapor pressure at a given temperature is said to be more volatile than the one exhibiting lower vapor pressure at the same temperature. Hence, the lower the normal boiling point, the higher the volatility, which is in turn inversely proportional to its fire point and the flash.

See also: Flammability Range Flash Point, Volatility, Flammability, and Explosive Properties.

Firewood

Firewood is any wood designated for, and used as, fuel but often refers to trees cut for that purpose. Seasoned firewood contains approximately 20% to 25% w/w moisture, compared to freshly cut or green wood, which can contain approximately 45% w/w moisture – green wood that has been recently cut and therefore has not had an opportunity to season (dry) by evaporation of the internal moisture. Softwood reaches good seasoning in six to twelve months, while hardwood takes longer. During this time, whether the wood rests on the forest floor or sits stacked and stored at a domestic location, wind and sun work to evaporate excess moisture.

Wood contains microscopic tubes that carry water from the roots through the tree. When a tree falls, water transportation ceases, but moisture remains. This moisture must evaporate to give you the best wood to burn. If you try to burn green wood, the heat produced will first attempt to dry the wood and then put any remaining energy into actually burning it, resulting in minimal heat output and increased creosote buildup in the chimney and flue.

When considering the type of wood for use as firewood, several characteristics are important. These include properties such as heat value, ease of splitting, weight per unit volume, ease of starting, and the amount of smoke produced. The moisture content of the wood, number of knots, and pitch content affect these characteristics of the more common woods used as firewood.

All woods dried to the same moisture content contain approximately the same heat value per pound which is on the order of 8,000 to 9,500 Btu for fully dried wood and 5,500 to 8,500 Btu for air-seasoned wood. However, the heat content of any fire depends on wood density, resin, ash, and moisture. Generally, one cord of well-seasoned hardwood (measuring 8 feet long, 4 feet high, and 4 feet wide or 128 cubic feet and weighing approximately two tons) burned in an airtight, draft-controlled wood stove with a 55 to 65% efficiency is equivalent to approximately 175 gallons of #2 fuel oil or 225 therms of natural gas consumed in a typical normal furnace having a 65 to 75% efficiency.

Forest biomass or agricultural residues are almost completely comprised of lignocellulosic molecules (wood), a structural matrix that gives the tree or plant strength and form. This type of biomass is a prime feedstock for combustion, and indeed remains a major source of energy in many parts of the world. The thermochemical platform utilizes pyrolysis and gasification processes to recover heat energy as well as the gaseous components of wood, known as synthesis gas or syngas. The synthesis gas can then be refined into synthetic fuels, including Fischer-Tropsch, methanol, and ethanol, through the process of catalytic conversion.

Fischer-Tropsch Process

The Fischer-Tropsch process is a catalytic chemical reaction in which carbon monoxide (CO) and hydrogen (H₂) in the synthesis are converted into hydrocarbon derivatives of various molecular weights. The synthesis gas that is required as the feedstock for the Fischer-Tropsch process is typically produced by gasification of coal, crude oil resid, biomass, organic waste, or by various reforming processes. The process can be represented by the simple equation:

In this equation, n is an integer. Thus, for $n = 1$, the reaction represents the formation of methane, which in most gas-to-liquid (GTL) applications is considered an undesirable by-product.

The Fischer-Tropsch process conditions are usually chosen to maximize the formation of higher molecular weight hydrocarbon liquid fuels which are higher value products. There are other side reactions taking place in the process, among which the water-gas-shift reaction is predominant:

Depending on the catalyst, temperature, and type of process employed, hydrocarbon derivatives ranging from methane to higher molecular paraffin derivatives and olefin derivatives can be obtained. Small amounts of low molecular weight oxygenated derivatives (such as alcohol derivatives and organic acid derivatives) are also formed. Typically, Fischer-Tropsch liquids are (unless the process is designed for the production of other products) hydrocarbon products (which vary from naphtha-type liquids to wax) and non-hydrocarbon products. The production of non-hydrocarbon products requires adjustment of the feedstock composition and the process parameters.

Briefly, synthesis gas is the name given to a gas mixture that contains varying amounts of carbon monoxide (CO) and hydrogen (H₂) generated by the gasification of a carbonaceous material. Examples include steam reforming of natural gas, crude oil residua, coal, and biomass. Synthesis gas is used as an intermediate in producing hydrocarbon derivatives via the Fischer-Tropsch for use as gaseous and liquid fuels.

The synthesis gas is produced by the gasification conversion of carbonaceous feedstock such as crude oil residua, coal, and biomass, and production of hydrocarbon products can be represented simply as:

However, before conversion of the carbon monoxide and hydrogen to hydrocarbon products, several reactions are employed to adjust the hydrogen/carbon monoxide ratio. Most important is the water gas shift reaction in which additional hydrogen is produced (at the expense of carbon monoxide) to satisfy the hydrogen/carbon monoxide ratio necessary for the production of hydrocarbon derivatives:

The boiling range of Fischer-Tropsch typically spans the naphtha and kerogen boiling ranges and are suitable for analysis by application of the standard test methods. With the suitable choice of a catalyst, the preference for products boiling in the naphtha range (<200°C, <390°F) or for product boiling in the diesel range (approximately 150 to 300°C, 300 to 570°F) can be realized.

Fischer-Tropsch Process – Catalysts

In the Fischer-Tropsch process, the temperature, pressure, and the catalyst type determines the chain polymerization versus chain termination ratio. This ratio governs the average molecular weight of the hydrocarbon mixture (syn-crude, synthetic crude oil) produced.

In fact, there is either a low temperature Fischer-Tropsch process (LTFT) or high temperature Fischer-Tropsch process (HTFT): (i) the low-temperature Fischer-Tropsch process operates at 200 to 240°C (390 to 465°F), and typically, an iron or cobalt catalyst is employed, and (ii) the high-temperature Fischer-Tropsch process operates HTFT: 300 to 350°C (570 to 660°F), and typically, an iron catalyst is employed. An increase in temperature leads to shorter chains (except at 330°C/625°F); mostly gasoline and olefins are produced; at 180 to 250°C (355 to 480°F) when mostly diesel and waxes are produced.

Several types of catalysts can be used for the Fischer-Tropsch synthesis. The most important catalysts are based on iron (Fe) or cobalt (Co). Cobalt catalysts have the advantage of a higher conversion rate and a longer life (over five years). The cobalt catalysts are in general more reactive for hydrogenation and produce therefore less unsaturated hydrocarbon derivatives and alcohols compared to iron catalysts. Iron catalysts have a higher tolerance for sulfur, are cheaper, and produce more olefin products and alcohols. The lifetime of the iron catalysts is short and in some commercial installations, may be measured in weeks.

Nickel oxide catalysts have high activity, are more selective toward shorter chains and will tend to the production of methane, and do not do well at higher pressures. Cobalt oxide is much more resistant to oxidation by oxygen and water giving it a higher activity and longer life than iron. Ruthenium catalysts favor selectivity of the gasoline and jet fuel- C₉-C₁₆ hydrocarbon derivatives using a supported zeolite matrix.

Manganese has been widely used as one of the promoters for the Fischer-Tropsch process on iron catalyst, particularly in producing low olefins. Efforts have also been exerted on the individual effect of manganese promotion on supported or unsupported iron catalysts. Iron-manganese (Fe-Mn) and cobalt-manganese (Co-Mn) catalysts favor the production of ethylene and butylenes and high yields for these olefins has been correlated with the iron manganese oxides phase and two carbide phases, while the manganese-rich solid has been correlated with two spinel phases and different carbide phases.

The iron-manganese catalyst, as one of the most important catalyst systems, has received extensive attention in recent years because of the higher olefin and middle distillation cut selectivity which allows their products to be used as a feedstock for the chemical industry. Therefore, the iron-manganese catalyst has a promising industrial application, and it is well known that higher selectivity of alkene derivatives can be obtained on iron-manganese catalysts than on other iron-based catalysts.

See also: Fischer-Tropsch, Fischer-Tropsch Process, Synthesis Gas.

Fischer-Tropsch Chemicals

Fischer-Tropsch chemicals are the products of the Fischer-Tropsch reaction in which synthesis gas (a mixture of carbon monoxide and hydrogen) is reacted to produce hydrocarbon derivatives and oxygenated species such as alcohols and ketones. The synthesis of hydrocarbon derivatives from synthesis gas (the Fischer-Tropsch synthesis) is a procedure for the indirect liquefaction of carbonaceous feedstocks.

The production of synthesis gas (syngas) involves the reaction of carbonaceous feedstock with steam and oxygen; the gas stream is subsequently purified (to remove sulfur, nitrogen, and any particulate matter) after which it is catalytically converted to a mixture of liquid hydrocarbon products. In addition, synthesis gas may also be used to produce a variety of products, including methanol.

Gasification may be attained by means of any one of several processes or even by gasification of the carbonaceous feedstock in place (underground gasification, in situ gasification). The exothermic nature of the process and the decrease in the total gas volume in going from reactants to products suggest the most suitable experimental conditions to use in order to maximize product yields.

In practice, the Fischer-Tropsch reaction is carried out at temperatures of 200 to 350°C (390 to 660°F) and at pressures of 75 to 4,000 psi; the hydrogen/carbon monoxide ratio is usually approximately 2.2:1 or 2.5:1. Since up to three volumes of hydrogen may be required to achieve the next stage of the liquids production, the synthesis gas must then be converted (by means of the water-gas shift reaction) to the desired level of hydrogen:

The gaseous mix is purified (for example, acid gas removal) and converted to a wide variety of hydrocarbon derivatives:

These reactions result primarily in low-boiling and medium-boiling range aliphatic compounds such as n-hydrocarbon derivatives as olefins and oxygenated products.

See also: Gasifiers, Gasification.

Fischer-Tropsch Process

In addition to carbonaceous feedstock and gas streams, biomass can also be used as a gasification feedstock to provide synthesis gas for the Fischer-Tropsch production of hydrocarbon derivatives and/or methanol. There are two routes for the production of synthetic fuels from gas streams (via synthesis gas) which are (i) the hydrocarbon derivatives route and (ii) the methanol route. Both routes often fall under the general umbrella description of the Fischer-Tropsch synthesis.

The Fischer-Tropsch process (or Fischer-Tropsch synthesis) is a catalyzed chemical reaction in which synthesis gas, a mixture of carbon monoxide and hydrogen, is converted into liquid hydrocarbon derivatives of various forms. The most common catalysts are based on iron and cobalt, although nickel and ruthenium have also been used. The principal purpose of this process is to produce a synthetic crude oil substitute from a carbonaceous feedstock for use as synthetic lubrication oil or as synthetic fuel. In fact, the combination of biomass gasification and Fischer-Tropsch synthesis is a possible route to produce renewable transportation fuels (biofuels).

The Fischer-Tropsch process involves a variety of competing chemical reactions, which lead to a series of desirable products and undesirable by-products. The most important reactions are those resulting in the formation of alkanes:

The process parameters and the catalyst composition are usually chosen, so as to favor higher order reactions ($n > 1$) and thus minimize methane formation. Most of the alkanes produced tend to be straight-chained, although some branched alkanes are also formed. In addition to alkane formation, competing reactions result in the formation of alkenes, as well as alcohols and other oxygenated hydrocarbon derivatives.

An important aspect of the Fischer-Tropsch process is the water-gas-shift reaction:

This reaction can be used to shift the hydrogen/carbon monoxide ratio of the synthesis gas. The initial reactants for the Fischer-Tropsch process (i.e., CO and H_2) can be produced by other reactions such as the partial combustion of a hydrocarbon:

For example (when $n = 1$), methane (in the case of gas-to-liquid applications):

Or by the gasification of biomass:

The energy needed for this endothermic reaction of carbonaceous materials (such as biomass and solid waste) and steam is usually provided by (exothermic) combustion with air or oxygen:

Generally, the Fischer-Tropsch process is operated in the temperature range of 150 to 300°C (300 to 570°F). Higher temperatures lead to faster reactions and higher conversion rates, but also tend to favor methane production. As a result, the temperature is usually maintained at the low to middle part of the range. Increasing the pressure leads to higher conversion rates and also favors formation of long-chained alkanes, both of which are desirable. Typical pressures are in the range of one to several tens of atmospheres. Chemically, even higher pressures would be favorable, but the benefits may not justify the additional costs of high-pressure equipment.

A variety of synthesis gas compositions can be used. For cobalt-based catalysts, the optimal hydrogen/carbon monoxide ratio is approximately 1.8-2.1. Iron-based catalysts promote the water-gas-shift reaction and thus can tolerate significantly lower ratios. This can be important for synthesis gas derived from biomass, which tends to have relatively low hydrogen/carbon monoxide ratios (<1).

In general, the product distribution of hydrocarbon derivatives formed during the Fischer-Tropsch process follows an Anderson-Schulz-Flory distribution:

$$W_n/n = (1-\alpha)^2 \alpha^{n-1}$$

A variety of catalysts can be used for the process – the most common catalysts are based on iron and cobalt, although nickel and ruthenium have also been used.

Cobalt seems to be the most active catalyst, although iron also performs well and can be more suitable for low-hydrogen-content synthesis gases such as those derived due to the promotion of the water-gas-shift reaction. Nickel can also be used, but tends to favor methane formation. In addition to the active metal, the catalysts typically contain a number of promoters, including potassium and copper, as well as high-surface-area binders/supports such as silica, alumina, or zeolites.

Thus, cobalt-based catalysts are preferred for Fischer-Tropsch synthesis when the feedstock is natural gas due to the higher activity of the cobalt catalyst. Natural gas has a high hydrogen-to-carbon ratio, so the water-gas-shift is not needed for cobalt catalysts. Iron catalysts are preferred for lower-quality feedstocks such as biomass. Iron catalysts are also susceptible to sulfur poisoning, but the lower cost of iron makes sacrificial catalyst at the front of a reactor bed economical. Iron can also catalyze the water-gas-shift to increase the hydrogen-to-carbon ratio to make the reaction more favorably selective. However, Fischer-Tropsch catalysts are notoriously sensitive to the presence of sulfur-containing compounds, and the sensitivity of the catalyst to sulfur is higher for cobalt-based catalysts than for their iron counterparts.

The Fischer-Tropsch product spectrum consists of a complex multi-component mixture of linear and branched hydrocarbon derivatives and oxygenated products. The main products are linear paraffins and α -olefins. The hydrocarbon synthesis is catalyzed by metals such as cobalt, iron, and ruthenium. Both iron and cobalt are used commercially at a temperature of 200 to 300°C (390 to 570°F) and at 150 to 900 psi.

Fischer-Tropsch Process – Chemistry

In the Fischer-Tropsch synthesis, hydrocarbon derivatives (C_xH_y) are synthesized from carbon monoxide (CO) and hydrogen (H_2) (synthesis gas, syngas). The Fischer-Tropsch process is an established technology and already applied on a large scale.

The number of chemical reactions involved in the manufacture of synthesis gas is large. The most important of these (limited to methane since it is the major constituents of natural gas) and given the objective of producing carbon monoxide and hydrogen from the methane, the most desirable reactions are those of reforming (Reaction 1) and partial oxidation (Reaction 3) producing hydrogen/carbon monoxide ratios of 3 and 2, respectively. If a source of carbon dioxide is available (or for gas streams rich in carbon dioxide) reforming with carbon dioxide (Reaction 2) provides a hydrogen/carbon monoxide ratio of 1. The data for higher molecular weight (higher boiling) hydrocarbon derivatives in some gas streams are correspondingly lower. The final hydrogen/carbon monoxide ratio is influenced further by the carbon monoxide shift reaction (Reaction 5).

Reforming (strongly endothermic):

Combustion (strongly exothermic):

Shift conversion (mildly exothermic):

Carbon formation:

The reforming reactions (1 and 2) are strongly endothermic and must be supported by the strongly exothermic reactions of partial oxidation (3) and/or complete combustion (4). The latter reaction is, however, in principle less desirable since neither hydrogen nor carbon monoxide is produced.

Thus, in the (exothermic) Fischer-Tropsch reaction, one mole of carbon monoxide reacts with two moles of hydrogen to afford a hydrocarbon chain extension ($-CH_2-$). The oxygen from the CO is released as product water:

The reaction implies a hydrogen-carbon monoxide ratio of at least 2 for the synthesis of the hydrocarbon derivatives. When the ratio is lower, it can be adjusted in the reactor with the catalytic water-gas-shift reaction:

When catalysts with water-gas-shift activity are used, the water produced in the reaction can react with carbon monoxide to form additional hydrogen. In this case, a minimal hydrogen-to-carbon monoxide (H_2/CO) ratio of 0.7 is required and the oxygen from the carbon monoxide is released as carbon dioxide:

The reaction affords mainly aliphatic straight-chain hydrocarbon derivatives (C_xH_y). Besides these straight-chain hydrocarbon derivatives, also, branched hydrocarbon derivatives, unsaturated hydrocarbon derivatives (olefins), and primary alcohols are formed in minor quantities. The kind of liquid obtained is determined by the process parameters (temperature, pressure), the kind of reactor, and the catalyst used. Typical operation conditions for the Fischer-Tropsch synthesis are a temperature range of 200 to 350°C (390 to 660°F) and pressures of 220 to 590 psi, depending on the process.

The Fischer-Tropsch process is a complicated process that requires a well-defined choice of reactors, catalysts, and operating conditions to synthesize the desired products. Even then, a mixture of compounds is obtained. The Fischer-Tropsch synthesis was originally operated in packed bed reactors. These reactors have several drawbacks that can be overcome by a slurry reactor. In these slurry reactors, the synthesis gas is bubbled through a suspension of catalyst particles (typically 30 to 50 micrometers) in an inert liquid. The heat of reaction is removed by circulating the slurry through external or internal heat exchangers. The slurry reactor can be operated at higher temperatures and at low H_2/CO ratios without problems due to efficient heat transfer and uniform temperatures. The application of small catalyst particles caused no occurrence of intra-particle heat and mass transfer resistances.

The Fischer-Tropsch synthesis in a slurry bubble column has several advantages over the fixed bed reactors. Because the Fischer-Tropsch process offers a number of advantages in slurry phase over the two-phase processes, special attention is paid to the effects of an inert liquid phase on the reaction rate, mass transfer, and product distribution.

See also: Fischer-Tropsch, Fischer-Tropsch Process, Synthesis Gas.

Fischer-Tropsch Process – Commercial Processes

The three main industrially proven processes involve various versions of tubular steam reforming, catalytic auto-thermal reforming, and non-catalytic partial oxidation.

In tubular steam reforming, the methane-steam reaction (reaction 1, above) takes place over a catalyst in a tube that is externally heated. A large steam surplus is required to suppress carbon formation in the catalyst. This tends to drive the carbon monoxide-steam shift reaction (reaction 5, above) to the right resulting in a hydrogen-rich synthesis gas. The heat is supplied largely by the undesirable complete combustion reaction of methane to carbon dioxide and water (reaction 4, above) outside of the tubes.

In catalytic auto-thermal reforming, oxygen is added to the feed. The heat requirement for the methane-steam reaction (reaction 1, above) is largely met by the methane-oxygen partial oxidation reaction (reaction 3, above) thus producing a lower hydrogen/carbon monoxide ratio in the synthesis gas. As in tubular reforming, considerable amounts of steam are required to suppress carbon formation. The absence of the metallurgical limitations of the catalyst tubes of a steam reformer allows higher operating temperatures thus reducing methane slip. At these higher temperatures, the carbon monoxide shift equilibrium is also more favorable to carbon monoxide than in the case of the tubular steam reformer.

In non-catalytic partial oxidation, the reaction of methane with oxygen (reaction 3, above) is dominant. The absence of any catalyst means that the process is tolerant of a small degree of carbon formation and allows even

higher operating temperatures. It is thus possible to operate partial oxidation without any steam addition, and the resulting synthesis gas is rich in carbon monoxide.

The art of selecting the most appropriate process (or a combination of processes) for synthesis gas generation consists of ensuring the correct gas specification as required by the selected synthesis while simultaneously minimizing certain inherent inefficiencies of the individual processes. In the case of tubular reforming, this inherent inefficiency lies in the use of external complete combustion requiring an expensive heat recovery train and still involving substantial losses in the stack gas. In the case of auto-thermal reforming and partial oxidation, the inefficiency lies in the energy requirement and investment for the oxygen plant.

The Synthol process has been operated at commercial scale since the 1950s by Sasol, and has undergone some evolution. The initial process, the Arge Process, involved low temperatures (200 to 250°C, 390 to 480°F), medium pressures, and a fixed catalyst bed. The process primarily produced a linear paraffin wax, which had use as petrochemical feedstock and also for transport fuels after further processing. This was the only process available until the 1950s/1960s when the Sasol Synthol process was developed and the process involved higher temperatures (300 to 360°C, 570 to 680°F) and medium pressures, but used a circulating fluidized bed to produce low-boiling olefin derivatives for chemicals production and gasoline components. This process has recently been updated to the Advanced Synthol process.

The latest development of Fischer-Tropsch technology is the Sasol slurry phase reactor, which is an integral part of the Sasol slurry phase distillate (SSPD) process, and carries out the synthesis reaction at low temperatures (200 to 250°C, 390 to 480°F) and low pressures.

The process involves bubbling hot synthesis gas through a liquid slurry of catalyst particles and liquid reaction products. Heat is removed from the reactor via coils within the bed producing steam. Liquid products are removed from the reactor, and the liquid hydrocarbon wax is separated from the catalyst. The gas stream from the top of the reactor is cooled to recover low-boiling hydrocarbon derivatives and reaction water. The Sasol slurry phase technology has undergone several developments primarily concerned with catalyst formulations. The initial development used an iron-based catalyst, but recent developments have used a cobalt-based catalyst, giving greater conversion.

The Shell middle distillate synthesis (SMDS) process is a two-step process that involves Fischer-Tropsch synthesis of paraffinic wax called the high-boiling paraffin synthesis (HPS). The wax is subsequently hydrocracked and isomerized (in the presence of hydrogen) to yield a middle distillate boiling range product in the high-boiling paraffin conversion.

In the high-boiling paraffin synthesis stage, wax is maximized by using a proprietary catalyst having high selectivity toward heavier products and by the use of a tubular, fixed-bed reactor. The high-boiling paraffin conversion stage employs a commercial hydrocracking catalyst in a trickle flow reactor. The high-boiling paraffin conversion step allows for production of narrow range hydrocarbon derivatives not possible with conventional Fischer-Tropsch technology.

The products manufactured are predominantly paraffinic, free from sulfur, nitrogen, and other impurities, and have excellent combustion properties. The high cetane number and smoke point indicate clean-burning hydrocarbon liquids having reduced harmful exhaust emissions. The process can also be proposed to produce chemical intermediates, paraffinic solvents, and extra high viscosity index lube oils.

The Lurgi combined reforming process was originally developed for large-scale methanol production, and it is with an example from this application that is described here. In the context of the production of liquid fuels, it is suitable as a building block for the methanol-to-gasoline (MTG) process or the olefins-to-gasoline, and distillates (MOGD) process. For the high-pressure Synthol process, carbon dioxide needs to be purged from the system. The conventional tubular steam reforming process as used for synthesis gas production produces a hydrogen/carbon monoxide ratio of over 4 and a stoichiometric ratio of 2.6 to 2.9 (i.e., a hydrogen-rich gas) depending on the quality of the feedstock gas stream.

Auto-thermal reforming or partial oxidation produces carbon monoxide-rich gases with a hydrogen/carbon monoxide ratio in the range 1.5 to 3.5 and a stoichiometric number of approximately around 1.8.

Approximately half the feed is processed in the tubular primary reformer. The other half, together with the primary reformer effluent, is auto-thermally reformed with pure oxygen in the secondary reformer. Besides matching hydrogen-rich and carbon monoxide-rich process steps to produce an optimum stoichiometric ratio, the Combined Reforming process has beneficial effects such as:

The methane slip of the overall reforming process is governed by the temperature of the secondary reformer that is not subject to the same limitations of tube metallurgy as the tubular reformer. The combined process can thus provide a lower methane slip. Less synthesis gas of the optimized quality is required per ton of methanol, reducing both the synthesis gas compressor load and the capital cost of the synthesis unit.

The operating temperature of the primary reformer need no longer be chosen to minimize methane slip. The reformer can be operated under mild conditions. The higher operating pressure thus possibly enables the synthesis gas compressor load to be further reduced.

The reduced throughput through the primary reformer together with the lower operating temperature combine to reduce the tubular reformer to approximately 25% of the size of that required for the single stage process. This reduces the stack gas losses referred to earlier by the same amount.

One feature common to all Fischer-Tropsch processes is the inherent lack of selectivity. The actual selectivity will depend on the desired product slate as well as on the catalyst and the operating conditions. In all cases, however, substantial quantities of gaseous hydrocarbon derivatives including methane are produced.

In principle, it is desirable to recycle these gaseous hydrocarbon derivatives to produce more synthesis gas. On the other hand, it is necessary to provide a purge of inert gases, principally argon and nitrogen. The other aspect of selectivity that requires recognition is that a proportion of higher molecular weight products, including waxes, is produced and may require hydrotreating for conversion to a saleable product.

The Syntroleum process is a cost-effective refinement of gas-to-liquid technology that has been in use for several decades. A major advantage is that the process uses compressed air instead of pure oxygen to facilitate the conversion reaction, substantially reducing the capital costs and vastly improving the safety of the process plants.

Fischer-Tropsch Process – Products

The subsequent chain-growth in the Fischer-Tropsch process is comparable with a polymerization process resulting in a distribution of chain-lengths of the products (Table F-4). In general, the product range includes the low-boiling hydrocarbon derivatives methane (CH_4), ethane (C_2H_6), propane (C_3H_8), and butane (C_4H_{10}), naphtha (C_5H_{12} to $\text{C}_{12}\text{H}_{26}$), kerosene-diesel fuel ($\text{C}_{13}\text{H}_{28}$ to $\text{C}_{22}\text{H}_{46}$), low molecular weight wax ($\text{C}_{23}\text{H}_{48}$ to $\text{C}_{32}\text{H}_{66}$), and high molecular weight wax ($>\text{C}_{33}\text{H}_{68}$). Linear alpha-olefins are also produced, but the distribution of the products depends on the catalyst and the process operation conditions (temperature, pressure, and residence time).

Table F-4 Range of Potential Fischer-Tropsch Products.

Carbon number	Product
C1-C2	Synthetic natural gas (SNG) Petrochemical feedstock
C3-C4	Liquefied petroleum gas (LPG) Petrochemical feedstock
C5-C7	Low-boiling naphtha
C8-C10	High-boiling naphtha
C11-C20	Middle distillate
C11-C12	Low-boiling kerosene
C13-C20	High-boiling kerosene
C21-C30	Soft wax
C31-C60	Hard wax

The (theoretical) chain length distribution can be described by means of the Anderson-Schulz-Flory equation:

$$\text{Log } W_n/n = 2 \log (\ln \alpha) + n \log \alpha$$

W_n is the weight fraction of chains with n carbon atoms and the chain growth probability factor (α) that is defined by:

$$\alpha = k_p/k_p + k_t$$

In this equation, k_p is the propagation rate and k_t is the termination rate.

Fischer-Tropsch Process – Product Separation and Upgrading

Conventional refinery processes can be used for upgrading of Fischer-Tropsch liquid and wax products. There are currently two well-defined routes of Fischer-Tropsch synthesis: (i) a low temperature process and (ii) a high temperature process. The first is employed in the production of waxes, which are converted into naphtha or diesel oil after the hydroprocessing. The second is employed in the production of gasoline and alpha-olefins. Fuels produced with the Fischer-Tropsch synthesis are of a high quality due to a low aromaticity and zero sulfur content.

The product stream consists of various fuel types which are (i) liquefied petroleum gas, LPG, (ii) gasoline, (iii) diesel fuel, and (iv) jet fuel as well as other products. Hydroprocessing is employed in the treatment of wax produced at a low temperature. The wax is basically composed of linear paraffin and small quantities of olefins and oxygenates. The hydrogenation of the olefins and the oxygenated compounds, besides hydrocracking of wax, can be conducted in conditions that are not very severe, with the production of naphtha and diesel oil.

Upgrading Fischer-Tropsch products is necessary for the conversion of heavier waxes into usable and lower-boiling products in the kerosene boiling range. Product upgrading is an optional stage added to the Fischer-Tropsch synthesis of gas-to-liquids (GTL) to increase the conversion and premium of the end product; it might not be necessary when the FB reactor is used paraffin synthesis.

For the separate production of Fischer-Tropsch fuels from synthesis, the synthesis gas is catalytically reacted over Fischer-Tropsch catalysts to produce hydrocarbon fuels in a slurry-phase reactor. The unconverted synthesis gas is then recycled to the synthesis unit to complete the conversion to fuels. The overall efficiency for this process on a higher heating value (HHV) basis is approximately 60%.

The liquid fuels consist of sulfur-free naphtha and high cetane diesel. By optimizing operating parameters, production of high-quality diesel fuel can be maximized. In these cases, the resulting fuel mix is one-third naphtha and two-thirds diesel fuel.

Although gas-to-liquids is an established technology, the biomass-to-liquids (BTL) process is a completely new approach, which requires the development of new technologies (biomass treatment, biomass gasification, hot gas clean up, new Fischer-Tropsch catalysts, advance wax upgrading) especially toward the reduction of the cost of the process. However, the big advantage of biomass-to-liquid fuels is that it is directly usable in the present day in transportation sector and furthermore, it may be suitable for future fuel cell vehicles via on board reforming since it is free of sulfur.

Biomass-to-liquids refineries can be located anywhere that carbonaceous feedstock is produced. This technology can produce clean transportation fuel using domestic coal thus expanding the supply of transportation fuels while decreasing dependence on overseas sources of energy.

Fischer-Tropsch Process – Reactors

The most important aspects for development of commercial Fischer Tropsch (F-T) reactors are the high reaction heats and the large number of products with varying vapor pressures (gas, liquid, and solid hydrocarbon derivatives).

For large-scale commercial reactors, heat removal and temperature control are the most important design features to obtain optimum product selectivity and long catalyst lifetimes. Over the years, basically four Fischer-Tropsch reactor designs have been used commercially.

The fixed bed reactor consists of thousands of small tubes with the catalyst as surface-active agent in the tubes. Water surrounds the tubes and regulates the temperature by settling the pressure of evaporation. The slurry reactor is widely used and consists of fluid and solid elements, where the catalyst does not have a particular position but flows around as small pieces of catalyst together with the reaction components. Overheating the catalyst causes the decrease of activity and favors the deposition of carbon on the surface of particles.

The fixed bed reactor produces 13.3% C_4 , 18% gasoline (C_5 - C_{11}), 14% diesel (C_{12} - C_{18}), 7% C_{19} - C_{23} , 20% medium wax, and 25% hard wax. Originally fixed reactors, later in the form of multi tubular fixed bed (MTFB) reactors, were used. In the multi tubular form, these reactors are commercially used by Sasol in South Africa and by Shell in Malaysia. The reactor operates in the three-phase gas-liquid-solid trickle bed mode. A recent development is the slurry bubble column (SBC) reactor which is used commercially by Sasol.

In the slurry reactor, the catalyst is suspended in the liquid and the gas is bubbled through the suspension. Generally, this type of reactor gives (i) a more uniform temperature, (ii) there is less catalyst present and consumed per ton of product, and (iii) the differential pressure over bed is lower.

The slurry reactor and the fixed bed reactor are used in low temperature process. The fluidized bed reactors are diverse, but characterized by the fluid behavior of the catalyst; the fluidized bed reactor is used in the high-temperature Fischer-Tropsch process.

Sasol uses iron catalysts and operates several types of reactors, of which the slurry bubble column reactor is the most versatile (i.e., applied in the Sasol Slurry Phase Distillate; SSPD).

The Fischer-Tropsch synthesis in slurry bubble column reactors is attractive relative to fixed bed reactors. The advantages are: i) low pressure drop over the reactor, ii) excellent heat transfer characteristics resulting in stable reactor temperatures, iii) no diffusion limitations, iv) possibility of continuous refreshment of catalyst particles, and v) relatively simple construction and low investment costs. Sixty-three percent straight run liquid fuel can be obtained from a slurry bubble column reactor, with a selectivity of 89% conversion of (H_2 + CO) per pass. The product upgrading process provides considerable flexibility of product option that includes high-quality diesel and jet fuel, chemicals for manufacturing solvents, alcohol, polymers, and specialty such as lube oils and waxes.

The slurry bubble column reactor is simpler in construction than the multi tubular fixed bed reactor. The suspended cooling coils and a gas distributor give a cheaper arrangement than the tube and tube sheet arrangement in the multi tubular fixed bed reactor. Because of this, the slurry bubble reactor column may lend itself much better to scale up.

Fluidized bed reactors are ideally suited for production of lower molecular weight long chain hydrocarbon derivatives from synthesis gas. The fluidized bed (FB) reactor produces 43% C_4 -, 40% gasoline (C_5 - C_{11}), 7% diesel, and 4% medium wax. These reactors can operate only when all the reactants are in gaseous phase. The catalyst used is typically a fused and promoted Fe-catalyst, and the reactors operate at high temperatures (high reaction rates) in order to avoid formation of high molecular weight products, which would wet catalyst particles and have an adverse effect on their fluidization properties.

Fixed-Bed Incinerator or Moving-Grate Incinerator

The fixed or moving grate incinerator is a large, fixed hearth incinerator with a moving grate. The moving grate enables the movement of waste through the combustion chamber to be optimized to allow a more efficient and

complete combustion. These incinerators are typically used for combustion of municipal waste, and are thus referred to as municipal solid waste incinerators (MSWIs).

In the fixed bed incinerator or moving grate incinerator, the waste is introduced by a crane through the throat at one end of the grate, from where it moves down over the descending grate to the ash pit in the other end. Here, the ash is removed through a water lock. Part of the combustion air (primary combustion air) is supplied through the grate from below. This air flow also has the purpose of cooling the grate itself. Cooling is important for the mechanical strength of the grate, and many moving grates are also water-cooled internally. Secondary combustion air is supplied into the boiler at high speed through nozzles over the grate. It facilitates complete combustion of the flue gases by introducing turbulence for better mixing and by ensuring a surplus of oxygen.

The incinerator must be designed to ensure that the flue gas reaches a temperature of at least 850°C (1,560°F) in order to ensure proper breakdown of organic toxins. This includes backup auxiliary burners (often fueled by oil), which are fired into the boiler in case the heating value of the waste becomes too low to reach this temperature alone. The flue gases are then cooled by heat transfer and heat the steam to typically 400°C at a pressure of 550 to 600 psi bar for the electricity generation in the turbine. At this point, the flue gas has a temperature of around 200°C, and is passed to the flue gas cleaning system.

See also: Combustion, Incinerators.

Fish Oil

Although long recognized as a source of nutrients, fish oil contains omega-3 fatty acids that can be absorbed easily. Fish oil contains both docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA). There is evidence from multiple studies supporting intake of recommended amounts of docosahexaenoic acid and eicosapentaenoic acid in the form of dietary fish or fish oil supplements which lowers triglycerides, reduces the risk of death, heart attack, dangerous abnormal heart rhythms, and strokes in people with known cardiovascular disease, slows the buildup of atherosclerotic plaques (hardening of the arteries), and lowers blood pressure slightly. Fish oil comes from cold water fish such as mackerel, tuna, salmon, cod, and many other fish.

Fish oil is also a potentially good source of fatty acids for the production of bio-oil. Waste fish oil can be converted into bio-oil by a fast pyrolysis process at 525°C (975°F) in a continuous pilot plant reactor with a yield on the order of 72% w/w. Many different chemical groups can be produced during the pyrolysis reaction, and the liquid product (bio-oil) obtained from triglyceride pyrolysis has a complex composition. This bio-oil can be used directly as fuel or can be fractionated to obtain purified hydrocarbon derivatives in the range of gasoline and diesel.

Fish oil is considered as one of the raw materials for the production of biodiesel as it contains more than 60 different fatty acids. Among which, nearly 80-85% of these are grouped into four category of fatty acids such as (i) C14:0 and C16:0, (ii) C16:1 and C18:1, (iii) C20:1 and C22:1, and (iv) C20:5, C22:5, and C22:6. Fish oil is enriched with eicosapentaenoic acid and docosahexaenoic acid, which represents more than 90% of all the polyunsaturated fatty acids. Thus, fish oil is potential feedstock for producing biodiesel.

Fixed-Bed Process

A fixed-bed (as applied to a reactor) is a stationary bed (of catalyst in the reactor) that is used to accomplish a process.

Fixed bed reactors resemble multi-tube heat exchangers, with the catalyst packed in vertical tubes held in a tube-sheet at the top and the bottom of the tubes. Uniform packing of catalyst within the tubes is important to ensure uniform pressure drop, flow, and residence time through each tube. Reaction heat is removed by generating steam on the shell side of the reactor, or by flowing some other heat transfer fluid through it. However, temperature control is more difficult in a fixed bed than in a fluid bed reactor because localized hot spots can develop in the tubes. The tendency to develop hot spots can be minimized by packing the reactor tubes with active catalyst and inert diluent mixtures in proportions that vary along the length of the tubes, so that there is low catalyst activity at the inlet, but the activity steadily increases to a maximum at the outlet. Another remedy is to pack the tubes with catalysts having

a progressively higher loading of cupric chloride so as to provide an activity gradient along the length of the tubes. Multiple reactors in series are also used in fixed bed oxy-chlorination, primarily to control heat release by staging the air or oxygen feed. Each successive reactor may also contain a catalyst with a progressively higher loading of cupric chloride. These methods of staging the air or oxygen feed and of grading the catalyst activity work to flatten the temperature profile and allow improved temperature control. Compared with the fluid bed process, fixed bed oxy-chlorination generally operates at a higher temperature (230 to 300°C, 445 to 570°F) and high gauge pressure.

See also: Fixed-Bed Reactor.

Fixed-Bed Reactor or Moving-Bed Reactor

In the fixed-bed reactor, the feedstock is supported by a grate and the gasifying media (steam, air, or oxygen) pass upward through the supported bed, whereby the product gases exit from the top of the reactor.

In the moving-bed reactor, the feedstock and gaseous streams move countercurrently, i.e., the carbonaceous feedstock moves downward by gravity and gas passes upward through the feedstock bed. The temperature at the bottom of the reactor is higher than that at the top. Because of the lower temperature at the top for feedstock devolatilization, relatively large amounts of liquid hydrocarbon derivatives are also produced in this type of gasifier.

In both types of the reactor, the residence time of the feedstock is much longer than that in a suspension reactor, thus providing ample contact time between reactants. Ash is removed from the bottom of the reactor as dry ash or slag – Lurgi and Wellman-Galusha gasifiers are examples of this type of reactors.

A moving bed reactor is classified as a kind of fixed-bed reactors since solids in the bed stay together as a bed regardless of the movement of the hardware that supports the bed.

See also: Gasification, Gasifiers.

Fixed Carbon

Fixed carbon is the combustible residue left after the volatile matter is driven off. It is, in fact, a measure of the solid combustible material in the carbonaceous feedstock after the expulsion of volatile matter and, like the determination of the carbon residue of crude oil and crude oil products, represents the approximate yield of thermal coke from the carbonaceous feedstock.

The fixed carbon value is one of the values used in determining the efficiency of the combustion equipment. It is a measure of the solid combustible material that remains after the volatile matter in the carbonaceous feedstock has been removed. For this reason, it is also used as an indication of the yield of coke in a coking process. Fixed carbon plus ash essentially represents the yield of coke.

The fixed carbon value is determined by subtracting from 100 the resultant summation of moisture, volatile matter, and ash with all percentages on the same moisture reference base (ASTM D3172). Fixed carbon values, corrected to a dry, mineral-matter-free basis, are used as parameters in the coal classification system (ASTM D388).

As an interesting comparison, the test for determining the carbon residue (Conradson), i.e., the coke-forming propensity of crude oil fractions and crude oil products (ASTM D189; ASTM D2416) advocates the use of more than one crucible. A porcelain crucible is used to contain the sample, and this is contained within two outer iron crucibles. This corresponds to the thermal decomposition of the sample in a limited supply of air (oxygen) and the measurement of the carbonaceous residue left at the termination of the test.

See also: Proximate Analysis.

Flammability

Flammability is the ease with which a substance will burn or ignite, causing fire or combustion. Flammable materials are materials (usually individual chemical or mixture of hydrocarbon derivatives) which have a low flash point and

ignite with little provocation. Hydrocarbon gases and liquid from any source are flammable insofar as they will burn readily in air. Any substance that can burn is considered flammable and/or combustible. The real threat of fire lies with flammable materials, which are substances that are more likely to burn and will ignite more rapidly.

The United States Department of Transportation (USDOT) is responsible for determining what constitutes a flammable material, and has offered the following definitions for ignitable materials:

Combustible Liquid

Any liquid having a flash point above 100°F and below 200°F

Flammable Liquid

Any liquid having a flash point below 100°F

Flammable Gas

A compressed gas that satisfies the criteria for flame projection, lower flammability limit, and flammability range

Flammable Solid

A non-explosive material that is capable of producing fire as a result of friction, heat retained from production or which, if ignited, produces a serious transportation hazard.

These definitions are based on the flammability characteristics of the material, specifically the *flash point* which is the minimum temperature at which a liquid gives off vapor in sufficient concentrations to allow the substance to ignite.

As an aid in identifying the chemicals which pose a flammability hazard in the laboratory, all chemical manufacturers are required to include relevant information on the chemical label. One of the most common grading systems is that developed by the National Fire Protection Association (NFPA). In this system, chemicals are rated from 0 (non-flammable) to 4 (extremely flammable) (Table F-5). It is important for all laboratory personnel to recognize and become familiar with the NFPA diamond and understand the grading levels established by the NFPA for flammable materials. The red portion of the diamond gives an indication of the flammability of the material.

Table F-5 The NFPA system for flammability rating.

Rating	Hazard Description
0	Materials that will not burn.
1	Materials that must be preheated before they will ignite.
2	Materials that must be moderately heated or exposed to relatively high ambient temperatures before they will ignite.
3	Liquids and solids that can ignite under almost all temperature conditions.
4	Materials which will rapidly vaporize at atmospheric pressure and normal temperatures, or are readily dispersed in air and which burn readily.

Another warning that indicates that a material is flammable is the presence of the flame on the chemical label. This is a standard symbol required by the United States Department of Transportation to be used on all packages offered for transport over public highways, airways, or by sea, which carry materials classified as an ignition hazard.

The flashpoint provides information related to the flammability of a chemicals or a crude oil product (Table F-6). Many of the common organic solvents and chemicals used in the laboratory have flash points well below room temperature. At or above the flash point temperature, there exists sufficient vapor, in correct concentration, to ignite if an ignition source is provided. Though the flashpoint provides a baseline for danger, other conditions may exist which would lower the flashpoint below the accepted value.

Table F-6 US DOT classification of flammable materials.

Classification	Terminology	Flash Point/Boiling Point
1A	Flammable	FP: <73°F; BP <100°F
1B	Flammable	FP: <73°F; BP >100°F
1C	Flammable	FP: 73°F; BP <100°F
II	Combustible	FP: at or >100°F
IIIA	Combustible	FP/BP: at or >140°F
IIIB	Combustible	FP/BP: at or >200°F

In mixtures of hydrocarbon derivatives, it is well worth remembering that the flash point of the mixture corresponds to the flash point of the most flammable (usually the lowest boiling) component of the mixture. Many workers and professionals use an average flash point for a mixture – much to their own detriment and the danger to themselves and colleagues.

It is important to recognize what constitutes an ignition hazard. Many fires occur because people are unaware of what is a hazard, or are careless when working with flammables around potential ignition sources. Each flammable substance has a corresponding flammable range at which concentrations a fire may result if an ignition source is at hand. The flammability range consists of an upper and lower concentration boundary that indicates where the danger lies – be the 2 limits. The flammability range is very wide for some chemicals – for example, acetaldehyde (CH_3CHO), carbon disulfide (CS_2), ether, (diethyl ether, $\text{C}_2\text{H}_5)_2\text{O}$), and methanol (CH_3OH). Such chemicals are particularly hazardous because the window for ignition is much wider – increased caution must be exercised when using these materials.

Flammability Range

The flammability range is expressed by the lower explosive limit (LEL) and the upper explosive limit (UEL). The lower explosive limit is the concentration of natural gas in the air below which the propagation of a flame will not occur on contact with an ignition source. The lower explosive limit for natural gas is 5% by volume in air, and, in most cases, the smell of gas would be detected well before combustion conditions are met. The upper explosive limit is the concentration of natural gas in the air above which the propagation of a flame will not occur on contact with an ignition source. The natural gas upper explosive limit is 15% by volume in air.

Flash Point

The flash point is the temperature to which gas must be heated under specified conditions to give off sufficient vapor to form a mixture with air that can be ignited momentarily by a specified flame (ASTM D56, ASTM D92, ASTM D93) – dependent on the composition of the gas and the presence of other hydrocarbon constituents.

Thus, the flash point is that minimum temperature at which there is a sufficient concentration of evaporated fuel in the air for combustion to propagate after an ignition source has been introduced. At this temperature, the vapor may cease to burn when the source of ignition is removed.

A slightly higher temperature, the fire point, is defined as the temperature at which the vapor continues to burn after being ignited, even when the source of ignition is removed. Neither of these parameters is related to the temperatures of the ignition source or of the burning liquid, which are much higher. The flash point is often used as one descriptive characteristic of liquid fuel, but it is also used to describe liquids that are not used intentionally as fuels.

Every flammable liquid has a vapor pressure, which is a function of temperature. As the temperature increases, the vapor pressure increases. As the vapor pressure increases, the concentration of evaporated flammable liquid in

the air increases. Hence, temperature determines the concentration of evaporated flammable liquid in the air under equilibrium conditions.

There are two basic standard (ASTM) test methods for measurement of the flash point measurement: (i) the open cup methods and (ii) the closed cup methods which produce the desired data.

In the open cup method, the sample is contained in an open cup which is heated, and at intervals, a flame is brought over the surface. The measured flash point will actually vary with the height of the flame above the liquid surface, and at sufficient height, the measured flash point temperature will coincide with the fire point. Examples include Cleveland Open Cup and Pensky-Martens open cup. The main difference is that the former is heated from below, while the latter is heated from the sides as well as from below.

However, the flash point is an empirical measurement rather than a fundamental physical parameter. The measured value will vary with equipment and test protocol variations, including temperature ramp rate (in automated testers), time allowed for the sample to equilibrate, sample volume, and whether the sample is stirred.

As with other properties, the flash point of a mixture, such as a gas stream or a low-boiling liquid mixture, is the flash point of the most volatile constituent in the mixture and, thus, is dependent on the composition of the gas stream and the presence of other constituents of the liquid mixture. The flash point is also used to detect contamination. A substantially lower flash point than expected for a product is a reliable indicator that a product has become contaminated with a more volatile product. The flash point is also an aid in establishing the identity of a particular product.

A slightly higher temperature, the fire point, is defined as the temperature at which the vapor continues to burn after being ignited, even when the source of ignition is removed. Neither of these parameters is related to the temperatures of the ignition source or of the burning liquid, which are much higher. The flash point is often used as one descriptive characteristic of liquid fuel, but it is also used to describe liquids that are not used intentionally as fuels.

See also: Fire Point and Flash Point, Flammability, Flammability Range.

Flash Pyrolysis

Pyrolysis is the thermal decomposition of organic substances by heating in the absence of air or an oxidizing agent, or with such a limited supply that gasification does not occur to an appreciable extent or may be described as partial gasification. A relatively low temperature is employed of 500 to 800°C (930 to 1,470°F), compared to 800 to 1,000°C (1,470 to 1,830°F) for gasification. Three products are usually produced: gas, pyrolysis oil, and a carbon-rich residue (char), the relative proportions of which depend very much on the pyrolysis method, the characteristics of the shale (kerogen) biomass, and the reaction parameters.

The premise is that when a carbonaceous material is heated very rapidly to temperatures in excess of those required for decomposition, fragmentation of the carbonaceous feedstock is very extensive thereby releasing the liquids from the carbonaceous feedstock matrix (and reducing the residence time of the liquids within the (solid) feedstock before secondary reactions to gaseous products can occur. This is especially true in view of the enhanced yields of volatile (liquid and gaseous) products that can be obtained, relative to the standard pyrolytic methods of the carbonaceous feedstock decomposition treatment as well as the standard thermal methods of the carbonaceous feedstock analysis (such as ASTM D3175).

Some of the techniques that are applicable to the flash pyrolysis are (i) laser, (ii) microwave, (iii) flash tube, (iv) plasma, (v) electric arc, (vi) shock tube, (vii) electric current, and (viii) entraining gas.

Lasers have been employed to produce extremely high temperatures as has microwave heating of carbonaceous feedstocks. Both techniques produce considerable quantities of acetylene, and the extent of the carbonaceous feedstock conversion depends on the volatile matter content of the carbonaceous feedstock, suggesting that the fixed carbon of the carbonaceous feedstock is not a predominant factor.

Flash tubes with short (microsecond or millisecond) irradiation times also produce acetylene as one of the major products, and there appears to be little tar production. The presence of hydrogen reduces the amount of acetylene produced.

Plasmas, which are often produced by exposing a gas stream to an electric arc, are capable of generating temperatures in excess of 10,000°C (>18,000°F). The extent of the reaction depends on the volatile matter content of the carbonaceous feedstock as well as on the particle size, and acetylene is the principal product – the yield of acetylene is increased by the presence of hydrogen.

Electric arc pyrolysis as a means of the carbonaceous feedstock decomposition is accomplished by passing a high-intensity electric arc between two electrodes, one of which is made of the carbonaceous feedstock. The products are mainly methane, acetylene, and ethylene with a notable absence of liquid products.

Shock tubes produce transient regions of high temperature and high pressure. The products from shock tube pyrolysis have been higher in the proportion of unsaturated hydrocarbon derivatives, but the overall conversion is low.

Techniques using an electric current as the source of heat usually attain lower temperatures than the previous methods, and the yields of acetylene are much lower. However, this technique has shown that (i) substantial yields of volatile matter can be achieved at high heating rates, (ii) hydrogen is the principal product of the carbonaceous feedstock decomposition at high temperatures, and (iii) the yields from hydrolysis of the carbonaceous feedstock are increased if the particle size of the carbonaceous feedstock is decreased.

The method using an entraining gas is amenable to commercial ventures. High conversion of the carbonaceous feedstock at 900°C (1,650°F) to volatile products (predominantly methane along with other hydrocarbon gases) has been reported. Although water is normally excluded along with other reagents during pyrolysis, the term hydrolysis has also been applied to the decomposition of organic material in the presence of superheated water or steam (hydrous pyrolysis).

The Karrick process is a low-temperature carbonization and pyrolysis process of carbonaceous materials. Although primarily meant for coal carbonization, it also could be used for processing of other carbonaceous materials. In the process, the feedstock is heated at 450 to 700°C (800 to 1,300°F) in the absence of air to distill out synthetic liquid fuel and gas.

Flash Vaporization

Condensate stabilization by flash vaporization is a relatively simple operation employing only two or three flash tanks. This process is similar to stage separation utilizing the equilibrium principles between vapor and condensate phases. Equilibrium vaporization occurs when the vapor and condensate phases are in equilibrium at the temperature and pressure of separation.

Condensate from the inlet separator after passing through the exchanger enters to the high-pressure flash tank, where the pressure is maintained at 600 psia. A pressure drop of 300 psia is obtained here, which assists flashing of large amounts of lower-boiling constituents, which join the sour vapor stream after recompression. The vapor can either be processed further and put into the sales gas or be recycled into the reservoir and used as gas lift to produce more crude oils. The bottom liquid from the high-pressure tank flows to the middle-pressure flash tank operated at 300 psia. Additional methane and ethane are released in this tank. The bottom product is withdrawn again to the low-pressure tank operated at 65 psia. To ensure efficient separation, condensate is degassed in the stripper vessel at the lowest possible pressure prior to storage. This reduces excess flashing of condensate in the storage tank and reduces the inert gas blanket pressure required in it.

Note that flash vaporization as a condensate stabilization method is old technology and is not often used in a modern gas cleaning plant. However, variations of flash technology might also be found on oil production facilities stabilizing liquid organic products.

Flax and Flaxseed Oil

Flaxseed is one of the richest plant sources of the ω -3 fatty acid, i.e., α -linolenic acid (ALA) and lignans (phytoestrogens). Flaxseeds are available in two basic varieties, which are (i) brown, and (ii) yellow or golden. Both have similar

characteristics and equal numbers of short-chain ω -3 fatty acids. The exception is a type of yellow flax called solin (trade name Linola), which has a completely different oil profile and has a low ω -3 fatty acid content. Brown flax is better known as an ingredient in paints, varnish, fiber, and cattle feed. Flaxseed is a multicomponent system with bio-active plant substances such as oil, protein, dietary fiber, soluble polysaccharides, lignans, phenolic compounds, vitamins (A, C, F, and E), and minerals (P, Mg, K, Na, Fe, Cu, Mn and Zn).

Flaxseed is the richest plant source of the ω -3 fatty acid, i.e., α -linolenic acid (ALA) but is low in saturated fatty acids, moderate in monosaturated fatty acids (18 %), and rich in polyunsaturated fatty acid. Of all lipids in flaxseed oil, α -linolenic acid is the major fatty acid followed by oleic, linoleic, palmitic, and stearic acids. Although flaxseed oil is naturally high in anti-oxidant like tocopherols and beta-carotene, traditional flaxseed oil gets easily oxidized after being extracted and purified.

The major insoluble fiber fraction consists of cellulose and lignin, and the soluble fiber fractions are the mucilage gums. The mucilage can be extracted by water and has good foam-stabilizing properties. Mucilage gums are polysaccharides that become viscous when mixed with water or other fluids.

Plant lignans are phenolic compounds formed by the union of two cinnamic acid residues. Lignans are ubiquitous within the plant kingdom and are present in almost all plants. Besides lignans, other phenolic compounds found in flaxseed are p-coumaric acid and ferulic acid.

Surplus biomass from the production of flax shives, and generated from *Brassica carinata*, a yellow-flowered plant related to those which engulf fields in spring, can be used to produce bioethanol. The shives, also known as shoves or boon, are the wooden refuse removed during processing flax, hemp, or jute, as opposed to the fibers (tow).

Flexible-Fuel Vehicle

A flexible fuel (or flex fuel) is an alternative fuel made of a combination (blend) of gasoline and methanol or ethanol. Thus, a flexible-fuel vehicle (flex-fuel vehicle or sometimes referred to as a dual-fuel vehicle) is a vehicle that can run alternately on two or more sources of fuel; it includes cars capable of running on gasoline and gasoline/ethanol mixtures, as well as cars that can run on both gasoline and methane-rich gas streams. Flexible fuel vehicles (FFVs) have an internal combustion engine and are capable of operating on gasoline and any blend of gasoline and ethanol up to 83%. E85 (or flex fuel) is a gasoline-ethanol blend containing 51% to 83% v/v ethanol, depending on geography and season.

Other than an ethanol-compatible fuel system and a different powertrain calibration, Flexible fuel vehicles are similar to their conventional gasoline-only counterparts. While fuel economy (miles per gallon) is generally lower with increased levels of ethanol (due to the lower energy content in ethanol as compared to gasoline and because the engines are optimized for gasoline), many flexible-fuel vehicles have improved acceleration performance when operating on higher ethanol blends.

Flexible-fuel engines are capable of burning any proportion of the resulting blend in the combustion chamber as fuel injection and spark timing are adjusted automatically according to the actual blend detected by electronic sensors. Flexible-fuel vehicles are distinguished from bi-fuel vehicles, where two fuels are stored in separate tanks and the engine runs on one fuel at a time, for example, compressed natural gas (CNG), liquefied petroleum gas (LPG), or hydrogen.

Typically, flexible fuel vehicles are designed to run on gasoline or a blend of up to 85% ethanol (E85). Except for a few engine and fuel system modifications, they are identical to gasoline-only models. Flexible fuel vehicles experience no loss in performance when operating on E85.

Flexsorb Process

The Flexsorb process is a process that uses sterically hindered amines (olamines) in aqueous solutions or other physical solvents; the molecular structure hinders the carbon dioxide approach to the amine and preferentially removes hydrogen sulfide from the gas stream.

The sterically hindered amines are secondary amines that have a large hydrocarbon group attached to the nitrogen group. The large molecular structure hinders the carbon dioxide approach to the amine. The larger the structure, the more difficult it becomes for the carbon dioxide to get close to the amine. They also appear to be unstable to the carbamate form of product and revert easily to the carbonate form found in the tertiary amines. Like tertiary amines, they are capable of a high degree of solvent loading – 1 mole/mole, instead of 0.5 mole/mole typical of primary and secondary amines.

The Flexsorb SE process is based on a family of sterically hindered amines in aqueous solutions or other physical solvents. The sterically hindered amines are secondary amines that have a large hydrocarbon group attached to the nitrogen group. The large molecular structure hinders the carbon dioxide approach to the amine. The larger the structure, the more difficult it becomes for the carbon dioxide to get close to the amine. They also appear to be unstable to the carbamate form of product and revert easily to the carbonate form found in the tertiary amines. Like tertiary amines, they are capable of a high degree of solvent loading—1 mole/mole, instead of 0.5 mole/mole typical of primary and secondary amines. One version of the solvent, Flexsorb SE Plus, is very selective toward hydrogen sulfide and has been used in several plants for tail gas processing or lean acid gas enrichment (AGE).

There are two mixed hindered amine/physical solvent versions of the Flexsorb process. The Hybrid Flexsorb SE process employs a solution of the Flexsorb SE amine, water, and an unspecified physical solvent. The Flexsorb PS solvent consists of a different hindered amine, water, and a physical solvent.

Flocculation

Flocculation is the further enlargement of agglomerated particles by either the presence of sticky metal hydroxides or the addition of an organic polymer. The suspension is gently mixed to allow bridges to form between particles which binds the particles together into larger agglomerates (flocs). The formation of these larger flocs is enhanced by mild mixing, while intense mixing breaks the bridges and redisperses the particles. Some additives such as aluminum sulfate (alum), ferric salts, and certain ionic polymers (polyelectrolytes) can enhance both agglomeration and flocculation.

The aluminum and iron salts hydrolyze to form insoluble aluminum or iron hydroxide gels, which form flocs that collect and trap colloidal materials. The polyelectrolytes are polymers of water-soluble organic molecules which are large organic molecules having polar groups spaced along their length. These polar groups can be cationic, anionic, or non-ionic. The ionic groups give the polymer water solubility as well as the ability to dissociate and form a polymer molecule with ionic charges spaced along its length.

The polymers work by dissociation of the ionic sites in the polymer, thus providing ionic charges on the polymer. The ionic charges then interact with the charge on the colloidal particles and form flocs by collecting a lot of individual particles to a single polymer molecule. They also bridge from one polymer molecule to another. Cationic polymers contain nitrogen in amine or quaternary ammonium groups as the active sites. Anionic polymers contain carboxylic, sulfate, sulfonate, phosphate, or any of the ionizable derivatives of mercaptan groups. The non-ionic polymers work by attracting the charges on the particles to the polar sites in the polymer, which normally contain oxygen as alcohol, ether, aldehyde, or ketone groups.

Flue Gas

Flue gas (sometimes called *exhaust gas* or *stack gas*) is the gas that emanates from combustion plants and which contains the reaction products of fuel and combustion air and residual substances such as particulate matter (dust), sulfur oxides, nitrogen oxides, and carbon monoxide. When burning coal and/or waste materials, hydrogen chloride and hydrogen fluoride may be present in the flue gas as well as hydrocarbon derivatives and heavy metal derivatives. In many countries, as part of a national environmental protection program, exhaust gases must comply with strict governmental regulations regarding the limit values of pollutants such as dust, sulfur and nitrogen oxides, and

carbon monoxide. To meet these limit values, combustion plants are equipped with flue gas cleaning systems such as gas scrubbers and dust filters.

As with other gases, the composition of flue gas depends on the type of fuel and the combustion conditions, e.g., the air ratio value. Many flue gas components are air pollutants and must therefore, due to governmental regulations, be eliminated or minimized by special cleaning procedures before the gas is released to the atmosphere. For example, flue gas produced by the combustion of fossil fuels, such as coal and crude oil, can contain a significant amounts of sulfur derivatives. In fact, when carbonaceous fuels, such as fossil fuels, are burned, approximately 90%+ w/w of the sulfur in the feedstock is converted to sulfur dioxide (SO_2), which occurs under normal conditions of temperature in the furnace and the oxygen fed to the combustor. However, when there is an excess of oxygen present, the sulfur dioxide is oxidized to sulfur trioxide (SO_3), and at higher temperatures (approximately 800°C, 1470°F), the formation of sulfur trioxide is favored.

As with other gases, the composition of flue gas depends upon the composition and properties of the fuel being combusted but, nevertheless, the composition will usually consist predominantly of nitrogen (usually on the order of 60% v/v and higher derived from the combustion process using air as the oxidant, carbon dioxide, and water vapor), as well as any excess oxygen (also derived from the air). Flue gas can also contain a small percentage of a number of pollutants, such as (i) particulate matter, for example soot, (ii) carbon monoxide, (iii) nitrogen oxides, NO_x , and (iv) sulfur oxides, SO_x . The potential for the presence of hydrocarbon derivatives is low unless the combustion process used a minimal of air and then also uses a hydrocarbonaceous feedstock. The particulate matter is composed of small particles of solid materials and small liquid droplets which give flue gases their smoky appearance. The nitrogen oxides are derived from the nitrogen in the ambient air as well as from any nitrogen-containing compounds in the fuel. The sulfur dioxide is derived from any sulfur-containing compounds in the fuel.

At power plants, flue gas is often treated with a series of chemical processes and scrubbers, which remove pollutants such as sulfur dioxide and sulfur trioxide. Flue gas desulfurization units capture the sulfur dioxide (and the sulfur trioxide, if present), and electrostatic precipitators or fabric filters remove particulate matter produced by burning fossil fuels, particularly coal. Nitrogen oxides are treated, either by modifications to the combustion process to prevent their formation, or by high temperature or catalytic reaction with ammonia (NH_3) or urea (H_2NCONH_2). In either case, the aim is to produce nitrogen gas, rather than nitrogen oxides. In the United States, there is a rapid deployment of technologies to remove mercury from flue gas (Scala et al., 2013). This is typically accomplished by absorption on sorbents or by capture in inert solids as part of the flue gas desulfurization process. Such scrubbing can lead to meaningful recovery of sulfur for further industrial use.

Examples of common flue gas cleaning processes are: (i) a wet scrubbing process, which uses a slurry of alkaline sorbent, usually limestone or lime, or seawater to scrub the gases, (ii) a spray-dry scrubbing process, which uses similar sorbent slurries as described in the first category, (iii) a wet sulfuric acid process, which allows the recovery of sulfur in the form of commercial-quality sulfuric acid, (iv) a process commonly referred to as a SNOX flue gas desulfurization process, which removes sulfur dioxide, nitrogen oxides, and particulate matter from flue gases, and (v) a dry sorbent injection process, which introduces powdered hydrated lime or other sorbent material into the exhaust ducts to eliminate sulfur dioxide and sulfur trioxide from the process emissions.

In terms of flue gas (and biogas) cleaning, the separation of the acid gaseous pollutants, the separation of hydrogen chloride, sulfur dioxide, and hydrogen fluorides (and any vestiges thereof), is essential. These gases form the greater part of the polluting constituents effected by absorption, preferentially by means of lime products [CaO , $\text{Ca}(\text{OH})_2$] and also by sodium-based products (NaOH , NaHCO_3 , and Na_2CO_3). The available gas cleaning processes for the absorption of the acid gaseous pollutants can be classified into the following three groups: (i) dry sorption, spray absorption/drying, and (iii) wet scrubbing.

The separation of the fly ash and the metals occurring in the form of particulate matter at the boiler outlet takes place likewise via filtration, so that this process step can be integrated into the absorption process for the acid gaseous pollutants. The separation of dioxins, furans, and those metals, in particular mercury, present in gaseous form at the boiler outlet generally takes place by adsorption on activated carbon, zeolites, open hearth furnace coke, or bentonite. For adsorption, either static or a moving bed adsorber unit or a filter layer adsorber unit may be employed which offers the possibility of integration of the adsorption process with the filtering out of fly ash and reaction products from the four basic gas cleaning concepts. Removal of nitrogen oxides (NO_x) from the flue gases can be achieved in conjunction with the above pollution control systems by the use of selective non-catalytic reduction (SNCR).

Flue gas composition depends upon the composition and combustion-related characteristics of fuels and the degree of completion of combustion. This is the function of design of combustion equipment - burner, furnace, and application.

Fuels from crude oil can be divided into two classes which are (i) natural gas and (ii) manufactured gas, their main source of heat being carbon and hydrogen. The manufactured crude oil fuels are designated according to their boiling range and applications. However, they are generally known by their commercial names like LPG, petrol/gasoline/gas, kerosene/luminosity oil, diesel/high speed diesel/light diesel, fuel oil/furnace oil, and bunker oil. The hydrogen and carbon contents of a particular boiling cut remain more or less the same everywhere; however, impurities like vanadium, magnesium, and iron vary from one source of crude to another. In general, CO_2 , SO_2 , N_2 , O_2 and steam/water vapors are the main constituents of flue gases. CO , SO_3 , oxides of vanadium, magnesium, and iron shall also appear in certain applications. In practice, two values of flue gas composition – theoretical and measured – are used for designing and planning of pollution control measures.

Two types of combustion processes are generally deployed – continuous and cyclic. In a continuous process, fuel is admitted through a burner to produce continuous flame and gases which heat the product by directly coming into contact with the charge. In the indirect method, heat from flue gas flows to the charge through the container. The cyclic combustion, a fixed quantity of fuel in the form of vaporized or atomized liquid droplets, is admitted into combustion space, burnt, and then the products of combustion after providing thrust to a piston leaves through a pipe and a silencer. This cycle is repeated with a fresh quantity of fuel. Each cycle takes a fraction of a second to complete. In case of cyclic combustion, time and combustion space are more important parameters.

Flue Gas Cleaning

The quantity of pollutants in the flue gas from incineration plants is reduced by several processes.

Particulate matter is collected by particle filtration, most often electrostatic precipitators and/or baghouse filters. Hydrogen chloride and sulfur dioxide are removed in scrubbers or as dry desulfurization by injection of limestone slurry into the flue gas before the particle filtration. Wastewater from scrubbers must subsequently pass through a wastewater treatment plant. Nitrogen oxide emissions are either reduced by catalytic reduction with ammonia in a catalytic converter or by a high temperature reaction with ammonia in the furnace. Heavy metals are often adsorbed on injected activated carbon, which is collected by the particle filtration.

Incineration produces fly ash and bottom ash just as is the case when coal is combusted. The total amount of ash produced by municipal solid waste incineration ranges from 15 to 20% by weight of the waste and the fly ash amounts to 0 to 10% of the total ash. The fly ash, by far, constitutes more of a potential health hazard than does the bottom ash because the fly ash often contains high concentrations of heavy metals such as lead, cadmium, copper, and zinc as well as small amounts of dioxins and furans. The bottom ash seldom contains significant levels of heavy metals.

While fly ash is always regarded as hazardous waste, bottom ash is generally considered safe for regular landfill after a certain level of testing defined by the local legislation. Ash, which is considered hazardous, may generally only be disposed of in landfills which are carefully designed to prevent pollutants in the ash from leaching into underground aquifers – or after chemical treatment to reduce its leaching characteristics.

In spite of the promise shown by the use of incinerators for waste disposal and, in some cases, energy production (in the form of fuel gases), the use of incinerators for waste management is controversial.

Flue Gas Desulfurization

Flue gas desulfurization (FGD or scrubbing) is the removal of sulfur oxides from stack gases of a coal-fired boiler which uses coal to produce steam for the steam turbines that drive their electricity generators.

A primary feature of flue gas desulfurization is that it offers relatively low marginal cost for the removal of sulfur dioxide, especially when at least 90% removal is desired for an extended period.

Sulfur dioxide is responsible for acid rain formation and, as a result of environmental protection regulations regarding sulfur dioxide emissions, sulfur dioxide is now being removed from flue gases by a variety of methods, of which the most common are (i) wet scrubbing using a slurry of sorbents such as limestone (CaCO_3) or lime (CaO) to scrub the gases, (ii) spray-dry scrubbing using similar sorbent slurries such as limestone (CaCO_3) or lime (CaO), (iii) wet sulfuric acid process recovering sulfur in the form of commercial quality sulfuric acid, and (iv) dry sorbent injection systems.

Most flue gas desulfurization systems employ two stages for: (i) the removal of fly ash and (ii) the removal of sulfur dioxide. In wet scrubbing systems, the flue gas normally passes first through a fly ash removal device, either an electrostatic precipitator or a wet scrubber, and then into the sulfur dioxide absorber. In dry injection or spray drying operations, the sulfur dioxide is first reacted with the sorbent and then the flue gas passes through a particulate control device.

In wet flue gas desulfurization systems, the flue gas exiting the absorber is saturated with water and still contains some sulfur dioxide, raising the possibility of corrosion of downstream equipment. Two methods that minimize corrosion are: (i) reheating the gases to above their dew point and (ii) choosing construction materials and design conditions that allow equipment to withstand the corrosive conditions.

Advanced flue-gas desulfurization processes remove acid gas from burning coal without expensive scrubbers. Emissions from burning coal are piped into an absorber, where the acid gases react with an absorbing solution (such as a mixture of lime, water, and oxygen).

In the process, the gas is usually passed through particulate removal equipment (such as an electrostatic precipitator) after which the flue gas is increased in pressure and then cooled from approximately 130°C (265°F) to 80°C (175°F). It enters the lowest part of the absorber and is further cooled by water used to wash the inlet duct to prevent a buildup of solids.

The main sulfur dioxide absorption process occurs as the gas is scrubbed by a recirculating limestone slurry. This is taken from the bottom of the absorber and is sprayed downwards from nozzles arranged at five separate levels in the absorber tower. As a result of the process chemistry, the recirculating slurry becomes predominantly gypsum (CaSO_4) and a portion is continuously pumped away for gypsum separation and the removal of water using a hydrocyclone system. A wastewater treatment plant ensures any water from the flue gas desulfurization process returned to the environment meets quality standards set by the regulatory authority.

Fluid Bed

The fluid-bed (fluidized bed) of catalyst or coke is a bed that is agitated by an upward passing gas in such a manner that the particles of the bed simulate the movement of a fluid and has the characteristics associated with a true liquid.

A fluidized bed is formed when a quantity of a solid particulate substance (usually present in a holding vessel) is placed under appropriate conditions to cause the solid/fluid mixture to behave as a fluid (fluidization of the solid). This is usually achieved by the introduction of pressurized fluid through the particulate medium. This results in the medium then having many properties and characteristics of normal fluids, such as the ability to free-flow under gravity, or to be pumped using fluid-type technologies.

A fluidized bed consists of a fluid-solid mixture that exhibits fluid-like properties. As such, the upper surface of the bed is relatively horizontal, which is analogous to hydrostatic behavior. The bed can be considered to be an inhomogeneous mixture of fluid and solid that can be represented by a single bulk density.

Furthermore, an object with a higher density than the bed will sink, whereas an object with a lower density than the bed will float, thus the bed can be considered to exhibit fluid behavior. The density (the solid volume fraction of the suspension) of the bed can be altered by changing the fluid fraction, and objects with different density comparative to the bed can be caused to sink or float by altering either the fluid or solid fraction.

In fluidized beds, the contact of the solid particles with the fluidization medium (a gas or a liquid) is greatly enhanced when compared to packed beds. This behavior in fluidized beds enables good thermal transport inside the system and good heat transfer between the bed and its container. Similarly to the good heat transfer, which enables thermal uniformity analogous to that of a well-mixed gas, the bed can have a significant heat-capacity while maintaining a homogeneous temperature field.

Fluidized beds are used as a technical process which has the ability to promote high levels of contact between gases and solids. In a fluidized bed, a characteristic set of basic properties can be utilized, indispensable to modern process and chemical engineering; these properties include: (i) a high surface area contact between fluid and solid per unit bed volume, (ii) a high relative velocity between the fluid and the dispersed solid phase, (iii) high levels of intermixing of the particulate phase, and (iv) frequent particle-particle and particle-wall collisions.

Fluid-Bed Boiler

A fluid-bed boiler (fluidized bed boiler) is a large, refractory-lined vessel with an air distribution member or plate in the bottom, a hot gas outlet in or near the top, and some provisions for introducing fuel; the fluidized bed is formed by blowing air up through a layer of inert particles (such as sand or limestone) at a rate that causes the particles to go into suspension and continuous motion.

Fluidized bed boiler systems convert biomass and other solid or liquid fuels into steam energy. A fluidized bed thermal oxidizer is combined with advanced heat transfer technologies to cleanly and efficiently generate steam energy.

In addition to biomass, the system can be designed to accommodate tire-derived fuel (TDF) and refuse-derived fuel (RDF) containing wires. Fuel ash characteristics and upset operating conditions inevitably lead to occasional clinkering of a portion of the bed media. If a clinker is allowed to accumulate, this material would eventually destroy the fluidizing properties of the bed by increasing the average particle size of the bed material to a point where fluidization could no longer occur.

Fluid-Bed Catalytic Cracking

The fluid catalytic cracking (FCC, fluid bed catalytic cracking) process is the most widely used process and is characterized by the use of a finely powdered catalyst that is moved through the reactor, and flow patterns may vary depending upon the precise configuration of the reactor. The catalyst particles are of such a size that when *aerated* with air or hydrocarbon vapor; the catalyst behaves like a liquid and can be moved through pipes. Thus, vaporized feedstock and fluidized catalyst flow together into a reaction chamber where the catalyst, still dispersed in the hydrocarbon vapors, forms beds in the reaction chamber and the cracking reactions take place. The cracked vapors pass through cyclones located in the top of the reaction chamber, and the catalyst powder is thrown out of the vapors by centrifugal force. The cracked vapors then enter the bubble towers where fractionation into cracked low-boiling and high-boiling gas oils, cracked gasoline, and cracked gases takes place.

Since the catalyst in the reactor becomes contaminated with coke, the catalyst is continuously withdrawn from the bottom of the reactor and lifted by means of a stream of air into a regenerator where the coke is removed by controlled burning. The regenerated catalyst then flows to the fresh feed line, where the heat in the catalyst is sufficient to vaporize the fresh feed before it reaches the reactor, where the temperature is approximately 510°C (950°F).

Fluid catalytic cracking is the workhorse of the modern refinery worldwide. It is used to convert a high-boiling viscous crude oil feedstock such as vacuum gas oil (VGO), atmospheric residue (AR), vacuum residue (VR), and deasphalted oil (DAO), into lower-boiling and more usable products such as low-boiling olefin derivatives, naphtha, and kerosene. Since its first commercialization over a half of century ago, the fluid catalytic cracking process is still an evolving technology. Improvements in the technology as well as changing feedstocks and product requirements continue to drive this evolution.

The fluid catalytic cracking process consists of two key units: a reactor and a regenerator. The preheated oil and steam are mixed and introduced to the bottom section of the riser using feed nozzles. At the feed injection zone of the riser, oil is mixed with a stream of hot regenerated catalyst flowing down the inclined standpipe from the regenerator. The oil is heated further by the hot catalyst and vaporized. It is at this point at which the cracking reactions

occur. The hydrocarbon vapors formed initially by vaporization and successively by cracking carry the catalyst up the riser at 10 to 20 m/s by dilute phase pneumatic transport. At the exit of the riser, the spent catalyst and hydrocarbon derivatives are quickly separated using cyclone devices. The spent catalyst, which is partially deactivated by coke deposition in the riser, and the vapor, enter a disengager. The vapor stream is routed to a cyclone where entrained catalyst and catalyst fines are separated, and the vapor is removed from the cyclone overhead. The hydrocarbon vapors are fractionated into various product streams: cracking gas, gasoline, diesel, cycle oil, and slurry oil. The cycle oil is sent back to the riser for further cracking. In some cases, part of the slurry oil is also routed to the riser.

The spent catalyst flows down into the stripper where entrained hydrocarbon derivatives are steam stripped and removed. The spent catalyst flows through the inclined stripper standpipe into a fluidized bed regenerator. In the regenerator, air is introduced and distributed throughout the bed. The coke deposited on the spent catalyst is burned off. The regenerated catalyst is then routed to the bottom of the riser via the regenerator standpipe, where it is mixed with the feed oil and the riser operation continues. The regenerator flue gas leaving the fluidized catalyst bed contains entrained catalyst particles. Before leaving the regenerator, the flue gas is routed to the cyclone system where most of the entrained catalyst is recovered and returned to the catalyst bed. All the modern fluid catalytic cracking units are equipped with the following features: (i) a pre-lifting zone, (ii) feed nozzles, (iii) short residence, (iv) a cyclone system, (v) reaction terminating technology, sometimes referred to as quench technology, and (vi) oxidation catalysts.

A pre-lifting zone is a special device at the bottom of the riser to enhance the contact of catalyst and hydrocarbon feedstock. Also, feed nozzles are important to achieve a well-dispersed feed oil into the riser reactor, especially for heavier feedstocks. A new-generation feed nozzle has been developed by incorporating the principle of vaporization to produce fine droplets of high-boiling oil at a narrow droplet size distribution; with a Sauter mean diameter (SMD; i.e. average particle size) of 50 to 70 μm .

A short residence time (on the order of 2 to 3 seconds) while cracking reactions occur in a riser at 500 to 530°C (930 to 985°F). In addition, the installation of a high efficiency cyclone system at the riser exit facilitates quick separation of catalyst and hydrocarbon vapors. This is to prevent undesirable cracking after the catalyst and hydrocarbon mixture exit the riser.

The reaction terminating technology (quenching technology) is used to minimize undesirable secondary cracking reactions by quenching the riser reactor. Quenching media such as gasoline, diesel, or water are injected into a pre-determined location at the middle section of the riser and/or at the riser exit. The latter is commonly referred to as post-riser quenching. Also, special oxidation catalysts are used in the regenerator at 680 to 720°C (1,255 to 1,330°F), which convert carbon monoxide in the flue gas to carbon dioxide.

The key process variables for the FCC reactions are feedstock properties, reaction temperature and residence time, regenerator temperature, and catalyst-to-oil ratio. However, for an existing FCC unit, the variability of regeneration temperature and catalyst-to-oil ratio is limited due to hardware considerations.

See also: Quench.

Fluid-Bed Catalytic Cracking Unit

The fluidized-bed catalytic cracking unit (FCCU) is by far the most common catalytic cracking unit. In the fluidized-bed process, oil and oil vapor pre-heated to 260 to 425°C (500 to 800°F) is contacted with hot catalyst at approximately 705°C (1,300°F), either in the reactor itself or in the feed line (riser) to the reactor. The catalyst is in a fine, granular form which, when mixed with the vapor, has many of the properties of a fluid. The fluidized catalyst and the reacted hydrocarbon vapor separate mechanically in the reactor, and any oil remaining on the catalyst is removed by steam stripping. The cracked oil vapors are then fed to a fractionation tower where the various desired fractions are separated and collected. The catalyst flows into a separate vessel(s) for either single- or two-stage regeneration by burning off the coke deposits with air.

Fluid-Bed Combustion

Fluid-bed combustion (fluidized bed combustion) is a process used to burn low-quality solid fuels in a bed of small particles suspended by a gas stream (usually air that will lift the particles but not blow them out of the vessel. Rapid

burning removes some of the offensive by-products of combustion from the gases and vapors that result from the combustion process.

Fluid-bed combustion is a means for providing high heat transfer rates, controlling sulfur, and reducing nitrogen oxide emissions due to the low temperatures in the combustion zone, which also favor the carbon dioxide equilibrium. Fluidized-bed combustion has the ability to reduce emissions by controlling combustion parameters and by injecting a sorbent, or a pollutant absorbent (such as crushed limestone), into the combustion chamber along with the coal.

In a fluid bed combustor, a gas passed slowly upwards through a bed of solid particles finds its way through the spaces between the particles and the pressure drop across the bed is directly proportional to the flow rate. If the flow rate is increased, a point is eventually reached at which the frictional drag on the particles becomes equal to their apparent weight (i.e., weight minus any buoyancy force); the bed then expands as the particles adjust their positions to offer less resistance to the flow. The bed is now said to be fluidized, and further increase in flow is not accompanied by an increase in pressure drop.

In a fluidized bed, heat and mass transfer between the fluidizing gas and the solid particles are extremely efficient. An additional advantage of fluidized-bed combustors is that they can use fairly coarse feedstock particles (approximately 0.04 in., approximately 1 mm diameter), and there is no need for much of the costly crushing equipment associated with the preparation of pulverized fuel.

A fluid bed combustor usually (in the initial stages) consists of sand or some similar inert material which is fluidized by an air stream and raised to the ignition temperature by an external heating source. When the requisite temperature is reached, the carbonaceous feedstock is fed to the vigorously bubbling bed where it becomes thoroughly mixed with the sand. As combustion begins, volatile material is given off and usually burns in the freeboard above the bed. The solid residue, or char, remains in the bed where the temperature is approximately 900°C (1650°F).

Ash from the carbonaceous feedstock and the residue from any limestone added to remove sulfur, together with the initial sand, are removed from the bottom of the bed, although organic and inorganic particles eventually become small enough to be carried over (entrained) in the flue gases. This fly ash has to be removed before these gases are discharged to the atmosphere; any unburned material represents a significant loss of efficiency, and arrangements are often made for recirculation of the fly ash.

Mechanical problems associated with fluidized combustion are encountered with the feeding of the carbonaceous feedstock and particularly with the withdrawal and separation of the ash from the char or unreacted the carbonaceous feedstock for recycling back to the combustion chamber.

The sulfur may be removed downstream with suitable ancillary controls, but capture during combustion (by adding limestone, CaCO_3 , or dolomite, $\text{CaCO}_3 \cdot \text{MgCO}_3$) to the bed) may be preferred.

The spent sorbent from fluidized bed combustion may be taken directly to disposal and is much easier than the disposal salts produced by wet limestone scrubbing. These latter species are contained in wet sludge having a high volume and a high content of salt-laden water. The mineral products of fluidized bed combustion, however, are quite dry and in a chemically refractory state, and, therefore, disposal is much easier and less likely to result in pollution.

The spent limestone from fluidized bed combustion may be regenerated thereby reducing the overall requirement for lime and thereby decreasing the disposal problem. Regeneration is accomplished with a synthesis gas (consisting of a mixture of hydrogen and carbon monoxide) to produce a concentrated stream of sulfur dioxide:

The calcium oxide product is supplemented with fresh limestone and returned to the fluidized bed. Two undesirable side reactions in the regeneration of spent lime produce calcium sulfide:

This results in recirculation of sulfur to the bed.

Ash agglomeration is not guaranteed as a means of ready separation and reducing bed carry-over; attrition occurs and particulates occur in the off-gases that require controls.

Combustion in a fluidized bed has some particular benefits including suitability for use with low-grade, high-ash carbonaceous feedstocks and lower bed temperatures compared to those in a conventional furnace. As a result of the lower temperature, the nitrogen oxide levels in the flue gas are reduced considerably.

Fluid-Bed Gasifier

In the fluidized bed gasifier, the fuel is fluidized using oxygen (or air) and steam. The ash is removed dry or as agglomerates. The temperatures are relatively low in dry ash gasifiers, so the fuel must be highly reactive. The agglomerating gasifiers have slightly higher temperatures, and are suitable for less reactive feedstock. Fuel throughput is higher than for the fixed bed, but not as high as for the entrained flow gasifier. The conversion efficiency is rather low, so recycle or subsequent combustion of solids is necessary to increase conversion. Fluidized bed gasifiers are most useful for fuels that form highly corrosive ash that would damage the walls of slagging gasifiers.

Fluid-Bed Incinerator

The fluidized bed incinerator uses a strong airflow through a sand bed until a point is reached where the sand particles separate to let the air through and mixing and churning occurs; thus, a fluidized bed is created and fuel and waste can now be introduced. The sand with the pre-treated waste and/or fuel is kept suspended on pumped air currents and takes on a fluid-like character. The bed is thereby thoroughly mixed and agitated keeping small inert particles and air in a fluid-like state. This allows all of the mass of waste, fuel, and sand to be fully circulated through the furnace.

The heat produced by an incinerator can be used to generate steam which may then be used to drive a turbine in order to produce electricity. However, the amount of energy produced is very much dependent upon the type and composition of the waste used as the feedstock. Much of the current thinking involves co-incineration of a specified amount of the waste (calculated on the basis of the carbon content of the waste) with, for example, coal to produce a consistent amount of energy.

Incineration has a number of outputs such as the ash and the emission to the atmosphere of flue gas. Before the flue gas cleaning, the flue gases may contain significant amounts of particulate matter, heavy metals, dioxins, furans, sulfur dioxide, hydrochloric acid, and polynuclear aromatic hydrocarbon derivatives (carcinogens).

The most publicized concerns related to the incineration of municipal solid wastes involve the fear that it produces significant amounts of emissions of dioxin derivatives and furan derivatives. These derivatives are considered by many to be serious health hazards. Older-generation incinerators that were not equipped with modern gas cleaning technologies were indeed significant sources of dioxin emissions. However, modern incinerators must limit and even mitigate such emissions.

Fluid-Bed Processes

In its simplest form, a fluidized bed may be thought of as a vessel containing particulate solid material into which a fluid is introduced. The fluid may be a liquid or a gas. When the fluid flowing at sufficient velocity contacts the solids, a suspension is formed that takes on certain fluid-like properties that the stationary bed of solids by themselves cannot attain. The suspension is termed a fluidized bed. The dynamic flow structure inside a fluidized bed will depend on the velocity of the fluidizing medium, which establishes the regime of fluidization in which the bed operates.

Gas is introduced through a distributor plate at the bottom of the bed. The distributor plate is designed to promote even gas distribution in the bed and to support the weight of the solids at rest.

At low velocities, the solids remain in a packed state. As the gas velocity is steadily increased, a point is reached where the upward force of the gas is sufficient to counteract the downward force of the bed mass and wall friction effects. At this point, the bed unlocks to form a gas-solid suspension. This is known as minimum or incipient fluidization, and the velocity at which it occurs, the minimum fluidization velocity.

The dynamic behavior of a bubbling fluidized may be quantified by fluctuations in bed pressure as measured with pressure transducers. A common plot used in the fluidization literature is the standard deviation of the pressure fluctuation versus gas velocity. The standard deviation increases with increasing velocity to a maximum, after which it decreases and then levels off. The increase in standard deviation is generally interpreted to be the result of the competing mechanisms of bubble coalescence and bubble break-up in the bed that leads to a high degree of variability. Beyond the maximum in standard deviation, bubble break-up dominates and well-defined bubbles are replaced with large voids. This is known as the turbulent regime. The voids rapidly form and disintegrate and move freely throughout the bed. This form of fluidization (i.e., without bubbles) leads to better gas-solid contacting and hence higher conversion in fluidized bed chemical reactors.

At still higher gas velocities, entrainment of the solid phase becomes significant. The solid particles are hence dispersed in the continuous gas phase. This regime of fluidization, known as the fast fluidization regime, is typified by the slip between solids and gas. Slip refers to the relative velocity between the solid and gas phases achieved by the downward-acting force of gravity, counteracting the upward drag force of the gas on the solids. For individual particles, the slip velocity is equal to the terminal settling velocity of a particle. However, it has been observed that the average slip velocity in a fast fluidized bed is an order of magnitude higher than the terminal velocity of a single particle. This has been attributed to the presence of particle clusters that tend to form in this regime of fluidization. The clusters are segregated to the wall where they flow downward, giving rise to high slip.

The final regime of fluidization is pneumatic transport. In this regime, the gas velocity is sufficiently high to transport all of the particles in the upward direction; there is no longer any downflow of solids at the wall. It has been suggested that the flow is dilute in the pneumatic transport regime, but the solid phase can also flow upward at the wall under high-density flow conditions.

Fluid-Bed Reactor

A fluid-bed reactor (fluidized bed reactor) is a type of reactor device that can be used to carry out multiphase chemical reactions. In this type of reactor, a fluid (gas or liquid) is passed through a granular solid material (usually a catalyst possibly shaped as tiny spheres) at high enough velocity to suspend the solid and cause it to behave as though it were a fluid (fluidization).

The solid substrate (the catalytic material upon which chemical species react) material in the fluidized bed reactor is typically supported by a porous plate (distributor). The fluid is then forced through the distributor up through the solid material. At lower fluid velocities, the solids remain in place as the fluid passes through the voids in the material. As the fluid velocity is increased, the reactor will reach a stage where the force of the fluid on the solids is enough to balance the weight of the solid material (incipient fluidization) and occurs at this minimum fluidization velocity and, once the minimum velocity is surpassed, the contents of the reactor bed expand and swirl around much like boiling water and the reactor is now a fluidized bed.

The advantages of fluid-bed reactors are (i) uniform particle mixing (ii) uniform temperature gradient, and (iii) ability to operate in a continuous state. However, as in any design, the fluidized bed reactor does have its drawbacks, such as: (i) increased reactor size, (ii) pumping requirements and pressure drop, (iii) particle entrainment, and (iv) erosion of internal components.

Fluidization can be registered exactly by measuring the pressure drop over the bed as a function of the gas velocity. In a packed bed reactor, the pressure drop increases monotonously with increasing gas velocity. At a minimum fluidization velocity, the increase in the pressure drop stagnates, and at even higher flow values, the pressure drop simply remains at this constant level. The minimum fluidization velocity and bed porosity in minimum fluidization are thus very central criteria in the design of fluidized beds.

Fluid-Bed Thermal Cracking

The first commercial use for fluidized thermal cracking dates back to the 1930s for coal gasification. Like other pyrolysis processes, the fluidized thermal cracking process burns waste with high combustion efficiency; however, it has a few other added advantages. Since it is a fluidized bed process, there is a rapid mixing of solid particles which enables a uniform temperature distribution; thus, the operation can be simply controlled. Fluidization also enhances the heat and mass transfer rates, which in turn, decreases the amount of carbon monoxide emitted.

In the process, a waste feedstock (such as crushed tire chips) is sent to the fluidized bed using a screw feeder. Air heated by a preheating furnace is fed to the reactor bottom in order to elevate the reactor temperature near cracking conditions [400 to 600°C (750 to 1,110°F)] before the chips are introduced. This enables the tire chips themselves to maintain the cracking temperature. A continuous cyclone is used to remove the char. The cracked gases are brought into contact with the recovered oil from the quench tower. Part of the recovered oil is recycled to the quench tower and the remainder sent to an oil storage tank for further purification. The uncondensed gas is sent to a treatment process to remove the hydrogen sulfide.

Fly Ash

Fly ash is the airborne components of ash produced in combustion processes that use carbonaceous feedstocks, and the fly ash is carried into the atmosphere by flue gases (also referred to as stack gases).

Fly ash contains toxic metals such as arsenic and cadmium. In the United States, the Clean Air Act requires that fly ash be removed from the emissions. As a result, antipollution devices such as air scrubbers, baghouses, and electrostatic precipitators are used to trap these pollutants. Baghouses work like giant vacuum cleaners, drawing emissions through giant fabric bags that trap the fly ash inside. Electrostatic precipitators use discharge electrodes (electrically charged parts of an electric circuit) to trap ash particles.

In an electrostatic precipitator, the electrodes are located between long, positively charged collection plates. As the fly ash passes between these collection plates, the discharge electrodes give each particle a negative charge. These negatively charged particles are then attracted to and held by the positively charged collection plates.

The removal of fly ash from combustion effluent streams is as important to the environment as the removal of sulfur oxides and nitrogen oxides. If not removed, the inorganic constituents and the organic constituents of the ash can cause serious environmental consequences, in addition to the solid particles acting as condensation nuclei and (catalytic) surfaces for the conversion of sulfur dioxide to the trioxide:

Depending upon the source and makeup of the material being burned, the components of fly ash vary considerably. Toxic constituents depend upon the specific feedstock.

Fly ash is composed of small ash particles that are carried in suspension in combustion products. However, depending upon the source and makeup of the material being burned, the components of fly ash vary considerably. Toxic constituents depend upon the specific feedstock.

Forage Crop

A forage crop is a crop of cultivated plants or plant parts, other than separated grain, produced to be grazed or harvested for use as feed for animals. The crops that are grown intensively with multiple cuttings per year include three major groups of (i) grasses, including cereals that are harvested green, (ii) legumes, including pulses that are harvested green, and (iii) root crops that are cultivated for fodder.

Furthermore, forage crops (e.g., forage sorghum, Sudan grass) hold promise for ethanol production because, in their early stage of growth, there is little lignin and the conversion of the cellulose to sugars is more efficient. In addition, the proportion of carbohydrates in the form of cellulose is less than in the mature plant.

Forage crops achieve maximum growth in a relatively short period; they can be harvested as many as four times in one growing season. For this reason, forage crops cut as green chop may have the highest yield of dry material of any storage crop.

In addition to cellulose, forage crops contain significant quantities of starch and fermentable sugars which can also be converted to ethanol. The residues from fermentation containing non-fermentable sugars, protein, and other components may be used for livestock feed.
